# **Evidence-based Dermatology**

Third edition

# Dedication

We, the editors, dedicate this book to our patients who have helped us to understand what it is really like to have a skin disease, and who have helped us to identify the questions that matter to them. Evidence-based dermatology starts with patients and ends with patients. If we lose our compassion for patients, we become a sounding brass or a tinkling cymbal.

# Evidence-based Dermatology

Foreword, xii

Preface, xiv

About the companion website, xv

## PART I

### The concept of evidence-based dermatology

*Andrew Herxheimer, editor*

- 1** The field and its boundaries, 3  
*Luigi Naldi*
- 2** The rationale for evidence-based dermatology, 7  
*Hywel C. Williams and Michael Bigby*
- 3** The role of patient and public involvement in evidence-based dermatology, 12  
*Carron Layfield, Amanda Roberts, Jason Simons, Colette O'Sullivan, Anjna Rani, and Kim Thomas*
- 4** The Cochrane Skin Group, 17  
*Finola Delamere, Liz Doney, Laura Prescott, and Shirley Manknell*

## PART II

### The critical appraisal toolbox

*Michael Bigby, editor*

- 5** Formulating well-built clinical questions, 25  
*Michael Bigby and Berthold Rzany*
- 6** Finding the best evidence, 27  
*Michael Bigby and Rosamaria Corona*
- 7** The hierarchy of evidence, 30  
*Michael Bigby*
- 8** Appraising systematic reviews and meta-analyses, 33  
*Michael Bigby and Hywel C. Williams*
- 9** How to critically appraise a randomized controlled trial, 39  
*Hywel C. Williams*
- 10** Assessing and explaining the evidence on harms of medical interventions, 46  
*Luigi Naldi*
- 11** How to evaluate diagnostic tests, 50  
*Joerg Albrecht and Michael Bigby*

- 12** What makes a good case series?, 54  
*Joerg Albrecht and Michael Bigby*

- 13** What makes a good prevalence survey?, 58  
*Hywel C. Williams*

- 14** Critical appraisal of pharmacoeconomic studies, 62  
*Rajini K. Murthy, Laura K. DeLong, and Suephy C. Chen*

- 15** Comparative effectiveness research: what it is and how to assess its quality, 66  
*Junko Takeshita and Joel M. Gelfand*

- 16** Outcome measures, 71  
*Alain Dupuy, Emilie Sbidian, and Sylvie Bastuji-Garin*

- 17** Where does qualitative research fit into evidence-based dermatology?, 75  
*Ray Jobling and Luigi Naldi*

- 18** Applying the evidence back to the patient, 79  
*Hywel C. Williams*

## PART III

### The evidence

#### SECTION 1: Common inflammatory skin diseases

*Luigi Naldi, editor*

- 19** Acne vulgaris, 87  
*Michael Romano and Robert P. Dellavalle*
- 20** Papulopustular rosacea, 106  
*Alfredo Rebora and Francesco Drago*
- 21** Perioral dermatitis, 112  
*Vincenzo Bettoli, Stefania Zauli, and Annarosa Virgili*
- 22** Hand eczema, 117  
*Wietske A. Christoffers, Marie-Louise Anna Schuttelaar, and Pieter-Jan Coenraads*
- 23** The primary prevention of atopic dermatitis, 127  
*Joanne R. Chalmers, Sam F. Bremmer, and Eric L. Simpson*
- 24** Atopic eczema, 136  
*Kim Thomas, Carolyn Charman, Helen Nankervis, Jane Ravenscroft, and Hywel C. Williams*
- 25** Seborrheic dermatitis, 169  
*Mauro Picardo and Norma Cameli*

- 26** Treatment of psoriasis, 175  
*Alexander Nast, Phyllis Spuls, and Tamar Nijsten*
- 27** Lichen planus, 200  
*Laurence Le Cleach and Olivier Chosidow*
- 28** Acute urticaria, 206  
*Torsten Schäfer*
- 29** Chronic urticaria, 210  
*Karsten Weller and Marcus Maurer*

## **SECTION 2: Skin cancer, moles, and actinic keratoses**

**Robert Dellavalle, editor**

- 30** Primary prevention of skin cancer, 223  
*Monika Janda and Adèle C. Green*
- 31** Treatment of cutaneous melanoma, 231  
*Mary Ann N. Johnson and April W. Armstrong*
- 32** Treatment of squamous cell carcinoma, 241  
*Louise Lansbury, William Perkins, and Fiona Bath-Hextall*
- 33** Basal cell carcinoma, 250  
*Fiona Bath-Hextall and William Perkins*
- 34** Primary cutaneous T-cell lymphoma, 264  
*Fiona Child and Sean Whittaker*
- 35** Actinic keratosis and Bowen's disease, 283  
*Sasha N. Jenkins, Maren Speck, and Suephy C. Chen*
- 36** Kaposi sarcoma, 303  
*Whitney A. High*
- 37** Melanocytic nevi, 313  
*Varun Shahi and Jerry D. Brewer*

## **SECTION 3: Infective skin diseases, exanthems, and infestations**

**Masutaka Furue and Yuping Ran, editors**

- 38** Local treatments for cutaneous warts, 320  
*Juping Chen and Yan Wu*
- 39** Molluscum contagiosum, 329  
*Minh L. Lam*
- 40** Impetigo, 337  
*Sander Koning, Renske van der Sande, Lisette W.A. van Suijlekom-Smit, and Johannes C. van der Wouden*
- 41** Athlete's foot, 341  
*Inajara Rotta, Michel F. Otuki, and Cassyano J. Correr*
- 42** Pityriasis versicolor, 345  
*Nancy Habib and Michael Bigby*
- 43** Onychomycosis, 349  
*Aditya K. Gupta, Elizabeth A. Cooper, Maryse Paquet, and Fiona Simpson*
- 44** Tinea capitis, 364  
*Urbà González*
- 45** Deep fungal infections, 371  
*Roderick J. Hay*
- 46** Streptococcal cellulitis/erysipelas of the lower leg, 378  
*Vinod E. Nambudiri and Michael Bigby*
- 47** Exanthematic reactions, 388  
*Sandra R. Knowles and Neil H. Shear*
- 48** Herpes simplex, 396  
*Vera Mahler*

- 49** Leprosy, 407  
*Saumya Panda*
- 50** Cutaneous leishmaniasis, 421  
*Urbà González, Armando Ruiz-Baqués, and Jorge Alvar*
- 51** Scabies, 432  
*Ian F. Burgess*
- 52** Head lice, 441  
*Ian F. Burgess and Ciara S. Casey*
- 53** Insect bites and stings, 451  
*Belen Lardizabal Dofitas*

## **SECTION 4: Disorders of pigmentation**

**Hywel C. Williams, editor**

- 54** Vitiligo, 464  
*Juan Jorge Manriquez and Sergio M. Niklitschek*
- 55** Melasma, 470  
*Asad Salim, Ratna Rajaratnam, and Eva Soos Domanne*

## **SECTION 5: Common ailments with significant cosmetic impact**

**Berthold Rzany, editor**

- 56** Male and female androgenetic alopecia, 486  
*Hans Wolff and Kathrin Giehl*
- 57** Alopecia areata, 490  
*Rod Sinclair*
- 58** Evidence-based treatment of hirsutism, 498  
*Ulrike Blume-Peytavi and Natalie Garcia-Bartels*
- 59** Focal hyperhidrosis, 504  
*Kave Shams and Berthold Rzany*
- 60** Dermal fillers, 512  
*Stephanie Ogden and Tamara Griffiths*
- 61** Reducing mimic wrinkles and folds with botulinum toxin A, 516  
*Berthold Rzany*

## **SECTION 6: Other important skin disorders**

**Michael Bigby, editor**

- 62** Cutaneous lupus erythematosus, 523  
*Susan Jessop and David Whitelaw*
- 63** Dermatomyositis, 531  
*Ruth Ann Vleugels, David F. Fiorentino, and Jeffrey P. Callen*
- 64** Acquired subepidermal bullous diseases, 545  
*Gudula Kirtschig, Vanessa Venning, Nonhlanhla P. Khumalo, and Fenella Wojnarowska*
- 65** Pemphigus, 552  
*Linda K. Martin, Brian R. Sperber, Dedee F. Murrell, and Victoria P. Werth*
- 66** Cutaneous sarcoidosis, 561  
*Misha Rosenbach and Joseph C. English III*
- 67** Erythema multiforme, 575  
*Pierre-Dominique Ghislain and Jean-Claude Roujeau*
- 68** Stevens–Johnson syndrome and toxic epidermal necrolysis, 578  
*Jean-Claude Roujeau, Pierre-Dominique Ghislain, and Laurence Valleyrie-Allanore*
- 69** Polymorphic light eruption, 586  
*Robert S. Dawe*

- 70** Infantile hemangiomas, 590  
*Hossain Shahidullah*
- 71** Pruritus, 595  
*Elke Weisshaar and Gil Yosipovitch*
- 72** Vulval lichen sclerosus, erosive lichen planus, and  
vulvodynia, 615  
*Rosalind C. Simpson, Ruth Murphy, and David Nunns*
- 73** Venous ulcers, 624  
*Jonathan Kantor, David J. Margolis, and Douglas J. Pugliese*
- 74** Other skin diseases for which trials exist, 632  
*Sinéad Langan and Hywel C. Williams*

## **PART IV**

### **The future of evidence-based dermatology**

*Luigi Naldi, editor*

- 75** Where do we go from here?, 637  
*Hywel C. Williams*

# Foreword

Twenty-eight years ago, when drafting an introductory chapter for a book on the effects of care during pregnancy and childbirth [1], I decided to use contrasting quotations from a distinguished statistician and a distinguished dermatologist. In 1952, Austin Bradford Hill had written [2]:

In my indictment of the statistician, I would argue that he may tend to be a trifle too scornful of the clinical judgement, the clinical impression. Such judgements are, I believe, in essence, statistical. The clinician is attempting to make a comparison between the situation that faces him at the moment and a mentally recorded but otherwise untabulated past experience.

Twenty years later, Sam Shuster coined the memorable phrase [3]:

Lies, damned lies and clinical impressions.

My draft went on to discuss the fundamental importance and great dangers of clinical impressions: in obstetric practice they have led both to important therapeutic discoveries and to iatrogenic disasters. I doubt that people treating skin disease have the capacity to do unintended harm on the scale achieved by obstetricians and neonatologists, but I also doubt there is any justification for complacency in matters of dermatological therapy.

The huge variability that exists in the management of common chronic skin diseases is clear evidence of collective uncertainty about the effects of alternative management strategies, even if a majority of individual clinicians are certain that they are doing the right thing. For example, I gather that fumaric acid esters have been used widely to treat psoriasis for over 40 years in Germany and the Netherlands, but that, although their use is supported by good evidence [4], they have hardly been used at all anywhere else. Some patients with warts are being put to the inconvenience (and expense) of attending hospital for cryotherapy; yet there is no strong evidence to suggest that they would be worse off treating their warts at home with salicylic acid paints [5]. Topical corticosteroid preparations like bethamethasone valerate are traditionally used twice daily, yet there is no good evidence to show that twice-daily applications are more effective than once-daily applications. Furthermore, once-daily applications are easier for people with eczema, they may result in fewer side effects, and they are also less costly [6]. As professionals are concerned to do more good than harm to their patients, all who treat skin disease have a duty to reduce uncertainty about the relative merits of alternative treatments by paying attention to the results of well-designed research.

To do right by their patients, people treating skin disease need to know what they know and what they don't know. This book tries to help them. Unlike traditional textbooks, it contains a toolbox section that describes the methods that have been used to review the evidence upon which conclusions about the effects of treatments have been based, and gives references to more detailed reports of the systematic reviews on which much of the text has drawn.

There is no consensus about the materials and methods that should be used to assemble evidence to support treatment recommendations published in textbooks and review articles, nor even

about the principles of systematic reviews. One senior dermatologist, for example, has written [7]:

The idea of a systematic review is a nonsense, and the sooner those advocates of it are tried at the International Court of Human Rights at the Hague (or worse still, sent for counselling), the better.

Unfortunately, those who express reservations about applying systematic approaches to the synthesis of research evidence tend not to outline the alternative strategies that they implicitly deem preferable. This is a serious matter because it has been shown that reviews using explicit methods reach conclusions that differ from traditional reviews, with implications that can be matters of life or death [8]. In dermatology, too, the conclusions of reviews in which efforts have been made to reduce biases and the effects of chance can differ from those reached in traditional reviews [9], and Cochrane systematic reviews have been shown to be higher quality than other systematic reviews [10]. In the light of this evidence, I believe that continued acquiescence in reviews that have not attempted to minimize biases and, where possible and appropriate, the effects of chance is not only scientifically unacceptable but also ethically highly questionable [11].

The contributors to this book have tried to control biases and – where they judged it appropriate – they have also reduced the effects of the play of chance by using statistical synthesis to analyze the results of similar but separate studies. As ways of improving the materials and methods used in such research synthesis are developed further, researchers will apply them, taking advantage of the potential offered by electronic media to publish full and transparent accounts of their work, and to respond to new data and suggestions for improving their analyses.

This third edition of *Evidence-based Dermatology* has extended coverage of topics from the second edition to include several additional and important skin disorders, such as molluscum contagiosum, pityriasis versicolor, onychomycosis, and vulval lichen sclerosus. And in the introductory section of the book, there are new chapters on outcome measures and qualitative research.

In laying bare just how much cannot be known on the basis of reliable evidence, the contributors to this book have also posed a very great challenge to everyone involved in treating skin disease. Can it be that a modest reduction in “doctor-assessed itch” is really the only demonstrable beneficial effect of the widespread use of evening primrose oil for people with eczema [12]? The book exposes the dearth of reliable studies addressing questions and outcomes that matter to patients, and it reveals the extent to which perverse incentives distort the dermatological research agenda. Those suffering from skin disease have every right to expect more from clinicians, researchers, and those who fund research. This book should help to provoke them to do better.

# Preface

When I started with the first edition of this book in 2001, evidence-based dermatology was a risky and controversial subject. It was new and threatening to some, and the topic was barely mentioned at large dermatology meetings where the case report was still king. Nowadays, everyone seems to be blurting out the word “evidence” in every other sentence. But what does it really mean in relation to good clinical dermatology care?

I am confident that this book will help you to make that bridge between good external evidence and the care of individual patients. Such integration is not easy in the messy realities of everyday life – the key is to try and to continue to enjoy lifelong learning.

For those of you new to *Evidence-based Dermatology*, you will find it a *different* sort of book to the usual textbook. Different in that we start the book by providing you with a detailed “toolbox” to help you understand the basic rudiments of *practicing* evidence-based dermatology. Our clinical chapter contributors then follow a common structure when summarizing the evidence base for different skin diseases. That structure begins with a clinical scenario, followed by clinical questions that lead to an evidence summary, based on the best possible evidence, such as systematic reviews and randomized controlled trials. Each summary includes a description of the possible benefits and drawbacks of individual treatment approaches followed by a view on the clinical implications of that evidence. It is a lot more work to write in this way than to let experts write what they like, but the success of the first two editions of this book suggests that you, the reader, appreciate such an approach. We have taken care, where possible, to separate the evidence found in studies from our opinions about that evidence, and we have tried

to help the reader by summarizing the key points at the end of each chapter.

For those of you familiar with the first and second editions of *Evidence-based Dermatology*, welcome back. In addition to providing evidence updates to chapters from previous editions, several new chapters appear in this third edition. In the toolbox section, there is now a chapter explaining all about comparative effectiveness research, another on outcome measures, and another describing qualitative research.

In the clinical section, there are new evidence summaries on molluscum contagiosum, pityriasis versicolor, onychomycosis, dermal fillers and wrinkles, and vulval disorders.

This third edition of *Evidence-based Dermatology* has been a labor of love for me, my associate editors, and chapter contributors, and I wish to thank them all for their efforts. None of us have contributed to this book for the money, but because of our motivation to create a stable record of what evidence-based dermatology is and how it can be applied to clinical practice. We have strived to keep the book as patient based as possible by discussing the evidence around commonly encountered patient scenarios. At the end of the day, it is patients who are at the heart of evidence-based dermatology. Please use this book in your clinic, rather than the library. If the book ends up dirty, torn, and fingered from daily use, we will be delighted.

## CHAPTER 1

# The field and its boundaries

Luigi Naldi

Centro Studi Gruppo Italiano Studi Epidemiologici in Dermatologia, Department of Dermatology, Ospedali Riuniti, Bergamo, Italy

### Introduction

Evidence-based medicine (EBM) represents the best way of linking and integrating clinical research with clinical practice. The results of clinical research should inform clinical practice. Ideally, whenever a clinical question has no satisfactory answer it should be addressed by clinical research. Since clinical questions are innumerable and resources are limited, the process needs some control, and priorities should be set using explicit and verifiable criteria. The public and purchasers have to be involved at this stage, and health needs and expectations in any given clinical area should be analyzed and taken into account. In many instances, confirmatory studies are needed and systematic reviews can be used to summarize study results, or to explore results in specific subgroups with a view to further research. The results of clinical research should be applied back to the individual patients in the light of their personal values and preferences. Communicational skills and patient understanding are key issues in this respect. In the real world, forces other than those involved in such an ideal process often distort research priorities and questions. For example, strong industrial and economic interests partly justify the lack of data on rare disorders or on common disorders if they occur mainly in poorer countries. This book may help to identify the more urgent questions that lack a satisfactory answer by summarizing for physicians (and patients) the best evidence available for the management of a large number of skin disorders – excluding sexually transmitted diseases, which are not regularly cared for by dermatologists. It can be thus be a starting point for rethinking the clinical research priorities in patient-oriented dermatology.

### What is special about dermatology?

The skin is not a simple inert covering of the body but a sensitive dynamic boundary and is an important organ of social and sexual contact. Body image is deeply rooted within the culture of any given social group and is profoundly affected by the appearance of the skin and its associated structures. The role skin appearance plays in

any given society is best understood from an anthropological perspective and using a narrative qualitative approach. This area is rather neglected in dermatological curricula.

Extensive disorders affecting the skin may disrupt its homeostatic functions, ultimately resulting in “skin failure,” needing intensive care. This is rare, but may happen, for example, with extensive bullous disorders or exfoliative dermatitis. The commonest health consequence of skin disorders is connected with the discomfort of symptoms – such as itching and burning or pain, which often accompany skin lesions and interfere with everyday life and sleep – and with the loss of confidence and disruption of social relations that visible lesions may cause. Feelings of stigmatization and major changes in lifestyle caused by a chronic skin disorder such as psoriasis have been repeatedly documented in population surveys [1,2].

### A vast array of clinical entities

Unlike most other organs that usually count around 50–100 diseases, the skin has a complement of 1000–2000 conditions, and over 3000 dermatological categories can be found in the International Classification for Disease version 10 (ICD-10). Part of the reason is that the skin is a large and visible organ. Beside disorders primarily affecting the skin, many major systemic diseases (e.g., of vascular and connective tissue) have cutaneous manifestations. Currently, the widespread use of symptom-based or purely descriptive terms, such as parapsoriasis or pityriasis rosea, reflects our ignorance and limited understanding of the causes and pathogenetic mechanisms of a large number of skin disorders. We still lack consensus on a detailed lexicon of dermatological terms for use in research and everyday clinical practice.

The ICD-10 revision dates back over 20 years to 1990. The new ICD-11 version due in 2014 should improve consensus. This review capitalizes on what three significant initiatives have achieved: (1) the Dermatologischer Diagnosenkatalog published in German-speaking countries by the Deutsche Dermatologische Gesellschaft and in English by the International League of Dermatological Societies; (2) the British Association of Dermatologists' diagnostic

index, first published in 1994 and updated annually since then; and (3) the Dermatology Lexicon Project, developed with a grant from the US National Institutes of Health, first published in 2005 and now supported by the American Academy of Dermatology [3].

### Extremely common disorders

Skin diseases are very common in the general population. Prevalence surveys have shown that they may affect 20–30% of the general population at any one time [4]. The most common diseases are also the most trivial ones. They include such conditions as mild eczematous lesions, mild to moderate acne, benign tumors and angiomas lesions. More severe skin disorders that can cause physical disability or even death are rare or very rare. They include, among others, bullous diseases, such as pemphigus, severe pustular and erythrodermic psoriasis, and such malignant tumors as malignant melanoma and lymphoma. The disease frequency varies according to age, sex, and geographic area. In many cases, skin diseases are trivial health problems compared with more serious medical conditions. However, as already noted, because skin manifestations are visible they may distress people more than do more serious medical problems. The issue is complicated because many skin disorders are not a yes or no phenomenon but occur in a spectrum of severity. The public's perception of what constitutes a "disease" requiring medical advice may vary according to cultural issues, the social context, resources, and time. Minor changes in health policy may have a large health and financial impact simply because many people may be affected. For example, most of the campaigns conducted to raise public awareness of skin cancer has greatly increased in the number of people having benign skin conditions such as benign melanocytic nevi evaluated and excised [5].

### Large variations in terms of health-care organization

Countries differ greatly in the way in which their health services deal with skin disorders. These variations are roughly indicated by the density of dermatologists ranging, in Europe, from about 1:20 000 in Italy and France to 1:150 000 in the UK.

In general, only a minority of people with skin diseases seek medical help, while many opt for self-medication. Pharmacists have a key role in advising the public on the use of over-the-counter products. Primary care physicians seem to treat most of those seeking medical advice. Primary care of dermatological problems is ill defined and overlaps with specialist activity. Everywhere the dermatologist's workload is concentrated in the outpatient department. Despite the vast number of skin diseases, just a few categories account for about 70% of all dermatological consultations [6].

Generally speaking, dermatology requires a low-technology clinical practice. Clinical expertise depends mainly on the ability to recognize a skin disorder quickly and reliably, which, in turn, depends largely on awareness of a given clinical pattern, based on previous experience and on the practiced eye of a visually literate physician [7]. The process of developing "visual skill" and a "clinical eye" is poorly understood, and these skills are not formally taught.

### Topical treatment may be possible

A peculiar aspect of dermatology is the possible option for topical treatment. This treatment modality is ideally suited to localized lesions, the main advantage being the restriction of the effect to the site of application and the limitation of systemic side effects. A

topical agent is usually described as a vehicle and an active substance, the vehicles being classified as powder, grease, liquid, or combinations such as pastes and creams.

Much traditional topical therapy in dermatology has been developed empirically with so-called magistral formulations. Most of these products seem to rely on physical rather than chemical properties for their effects, and it may be an arbitrary decision to consider one specific ingredient as the "active" one. Physical effects of topical agents may include detergency, hydration, and removal of keratotic scales. The border between pharmacological and cosmetic effects may be blurred, and the term "cosmeceuticals" is sometimes used [8]. In addition to drug treatment, various non-drug treatment modalities exist, including phototherapy or photochemotherapy and minor surgical procedures such as electrodesiccation and cryotherapy. Large variations in treatment modalities for the same condition mainly reflect local traditions and preferences [9].

### Limitations of clinical research

As in other disciplines, the last few decades have seen an impressive increase in clinical research in dermatology. However, the upsurge of clinical research has not been paralleled by methodological refinements; for example, the quality of randomized control trials (RCTs) in dermatology seems to fall well below the usually accepted standards [10]. Innovative thinking is needed in dermatology to make clinical research address the important issues and not simply ape the scientific design.

### Disease rarity

In at least 1000 rare or very rare skin conditions no single randomized trial has been conducted. These conditions are also those carrying a higher burden of physical disability and mortality. Many of them have an annual incidence rate of below one case per 100 000 and frequently below one case per million. International collaboration and institutional support are clearly needed, but so far such efforts are very few.

### Patients' preferences

One alleged difficulty with mounting randomized clinical trials in dermatology is the visibility of skin lesions and the consideration that, much more than in other areas, patients self-monitor their disease and may have preconceptions and preferences about specific treatment modalities [11]. The decision to treat is usually dictated by subjective issues and personal feelings. There is a need to educate physicians and the public about the value of randomized trials to assess interventions in dermatology. Motivations and expectations are likely to influence clinical outcomes of all treatments, but they matter more in situations where "soft end-points" matter, as in dermatology. Commonly, more than 20% of patients with psoriasis entering randomized clinical trials "improve" on placebo independently of the initial disease extension [12]. Motivations are equally important in pragmatic trials evaluating different packages of management, such as in the comparison of a self-administered topical product for psoriasis with hospital-based therapy like phototherapy. Traditionally, motivation as a characteristic of the patient that is assumed not to change with the nature of the intervention. However, it is more realistic to view motivation in terms of the "fit" between the nature of the treatment and the patient's wishes and perceptions, especially with complex interventions requiring the patient's active participation [13]. The public is

inundated with uncontrolled and sometimes misleading or unrealistic messages on how to make the body look better. The design and analysis of clinical trials must properly consider patients' motivations and what they are told.

### The use of placebo in randomized control trials

Too many placebo-controlled RCTs are conducted in dermatology even when alternative therapies exist [14,15]. As a consequence, many similar molecules used for the same clinical indications can be found in some areas; for example, topical steroids. Many regulatory agencies still regard placebo controls as the "gold standard." There is a need to establish criteria for the use of placebo in dermatology. They should be used with the active and informed participation of the public and should be considered by ethics committees and regulatory agencies. "Pragmatic" randomized trials conducted under conditions close to clinical practice and contrasting alternative therapeutic regimens are urgently needed to guide clinical decisions.

### Long-term outcome of chronic disorders

Several major skin disorders are chronic conditions where no cure is currently available. Whenever a definite cure is not reasonably attainable, it is common to distinguish between short-term, intermediate (usually measurable within months), and long-term outcomes. Long-term results are not simply predictable from short-term outcomes. Many skin disorders wax and wane over time, and it is hard to define what represents a clinically significant long-term change in the disease status. This is even more difficult than defining outcome for other clinical conditions, such as cancer or ischemic heart disease, where death or major hard clinical end-points (e.g., myocardial infarction) are of particular interest. In the long term, the way the disease is controlled and the treatment side effects are vitally important, and simply and cheaply measured outcomes applicable in all patients are more appropriate. These may include the number of patients in remission, the number of hospital admissions or outpatient consultations, and major disease flare-ups. Drop-outs merit special attention since they may strongly reflect dissatisfaction with treatment.

### Self-control design

Study designs that are often used at a preliminary stage in drug development are *within-patient control studies*; that is, crossover and self-controlled studies or simultaneous within-patient control studies. In dermatology they are also used, albeit improperly, at a more advanced stage. In a survey of more than 350 published RCTs of psoriasis, a self-controlled design accounted for one-third of all the studies examined and was relied on at some stage in drug development [14]. The main advantage of a within-patient study over a parallel concurrent study is statistical. A within-patient study attains the same statistical power with far fewer patients, and at the same time reduces variability between the populations 'confronted' [15]. Within-patient studies may be useful when studying conditions that are uncommon or show high degree of patient-to-patient variability. On the other hand, within-patient studies impose restrictions and artificial conditions, which may undermine validity and generalizability of results and may also raise some ethical concern. The washout period of a crossover trial as well as the treatment schemes of a self-controlled design, which entails applying different treatments to various parts of the body, do not seem to be fully justifiable from an ethical point of view. Clearly, the impractical treatment modalities in self-controlled studies or the washout

period in crossover studies may be difficult for the patient to accept. Drop-outs may have more pronounced effects in a within-patient study than in other study designs because each patient contributes a large proportion of the total information. The situation is compounded in self-controlled studies, where the dropping out from the study may be caused by observing a difference in treatment effect between the parts into which the patient has been "split up." In this case, given that drop-outs are related to a difference in treatment effect between interventions, the effect of the intervention is liable to be underestimated.

### The increasing role of industry-sponsored trials

The pharmaceutical industry's influence on medical research has increased enormously in the last decades. Dermatology is no exception. As indicated by the European Dermatoepidemiology Network psoriasis project, only a quarter of all randomized clinical trials published on psoriasis from 1977 to 2000 have been conducted without direct pharmaceutical companies' sponsorship, and the proportion of sponsored trials has increased dramatically in more recent years [14,16]. Evidence from systematic reviews show that published studies funded by pharmaceutical companies are several times more likely to have results favorable to the company than studies funded from other sources [17].

Selective presentation of scientific data, statements by opinion leaders in sponsored symposia and involvement of patient organizations in sponsored campaigns are among the promotional strategies adopted to expand the market once limited clinical evidence has been collected on a new agent. Heavy marketing competition has been paralleled by a cycle of increasing collusion between physicians, academic opinion leaders, patients' organizations, researchers, and industrial interests [18,19].

The recognition of the problems involved with new drug registration and the lack of long-term data on effectiveness and safety have prompted the starting of registries and postmarketing surveillance programs closely linking prescription to the provision of patient data at first drug prescription and on a regular basis subsequently during a predefined follow-up period. Psoriasis registries are a successful example [20].

### The limitations of systematic reviews

The large number of clinical studies in dermatology and the lack of consensus on the management of many skin disorders point to systematic reviews as a way to improve the evidence and guide clinical decisions. However, systematic reviews alone cannot be expected to overcome the methodological limitations in dermatological research we have pointed to. On the contrary, there are some indications that systematic reviews, if not properly guided by important clinical questions, might amplify the unimportant issues and may result in a rather misleading scale of evidence to guide clinical decisions. Since most RCTs are performed by pharmaceutical companies, it is quite plausible that data-driven systematic reviews will reflect the priorities as perceived by pharmaceutical companies and not necessarily by the public and clinicians. Without a change in regulatory procedures, pharmaceutical companies will continue to pay little attention to comparative RCTs and will continue to assess drugs for indications which are worth the financial investment, neglecting rare but clinically important disorders [21].

Systematic reviews alone cannot fill the gap, and we urgently need primary research and high-quality and relevant clinical trials. In recent years, the problem has been acknowledged, and we have

seen the upsurge of initiatives in our discipline to develop independent clinical trial research networks [22–24] and, more recently, the promotion of an international federation of these networks to promote collaboration and to improve the quality and reporting of clinical research at an international level.

### Evidence-based medicine: where do we go from here?

An EBM approach should permeate medical education and inform academic medicine. Only if such a change is promoted can EBM become central to clinical practice and not trivialized to “cook-book” medicine. If EBM is successfully integrated into everyday practice it may become easier to conduct primary clinical research based on clinical needs rather than on commercial interests.

In primary research, more imaginative and effective research instruments are needed, and research strategies should be developed that take account of the peculiarities of dermatology compared with other disciplines. Qualitative research should not be neglected. It is the key to understanding what matters to patients, the intercultural variations in body image and how health needs for skin diseases are expressed and perceived in different situations.

## What is evidence-based dermatology?

### Definitions

Sackett, a clinical epidemiologist and one of the founders of modern evidence-based medicine (EBM), defined the latter as “the conscientious, explicit and judicious use of current best evidence about the care of individual patients” [1].

Sackett’s definition is still one of the best, because it reflects a number of key concepts:

- “Conscientious” implies an *active* process that requires learning, doing, and reflection.
- “Explicit” implies that we can describe and replicate the *process* that is used to practice EBM.
- “Judicious” denotes the need for clinical judgment in applying evidence.
- “Current” implies being *up to date*.
- “Best” implies that we should seek the most *reliable* evidence source to inform practice.

As Chapter 18 elaborates, perhaps the most important and frequently forgotten phrase in this definition is “the care of individual patients.” The place for EBM is not in trying to score intellectual points in the literature or in humiliating colleagues at journal clubs; it is at the bedside or in the outpatient consulting room. As Chapter 75 emphasizes, EBM is a way of thinking and working, with improved health of patients as its central aim.

Nowadays, the term “evidence-based practice” is often used instead of EBM. The term “evidence-based practice” is a good phrase as it emphasizes the *doing* rather than *talking* about EBM, and may be defined as integrating one’s clinical expertise with the best external evidence from systematic research [2]. Evidence-based dermatology (EBD) simply implies the application of EBM principles to people with skin problems [3].

### What evidence-based dermatology is not

Despite the above clear definitions, the purpose of EBD is often misunderstood in the literature [4]. Some of these misinterpretations are shown in Box 2.1. First, EBD does not tell dermatologists what to do [1]. Even the best external evidence has limitations in informing the care of individual patients. To use R.E. Clerk’s meta-

phor, external evidence is just one leg of a three-legged stool – the other two being the clinician’s expertise and the patient’s values and preferences. Take one of those legs away, and the stool falls down. Clinical expertise and discussion of what matters most to patients in their choice of treatment options will always be at the heart of applying evidence during a dermatology consultation. EBD is not a cookbook of recipes to be followed slavishly, but an approach to medicine that is patient driven from its outset. Patients are the best sources for generating the important clinical questions, answers to which then need to be applied back to such patients [5].

Just as ordinary patients are at the heart of framing evidence-based questions, so too are ordinary clinical dermatologists at the heart of the practice of EBD [6]. EBD is not something that only an exclusive club of academics with statistical expertise can understand and practice, but rather it is something that all dermatologists can practice with appropriate training. Being able to critically appraise a published clinical trial or systematic review about a new dermatological treatment is a core competency that is as basic to being a dermatologist as the ability to examine, diagnose, or perform a skin biopsy.

Contrary to popular belief, the prime purpose of EBD is not to cut costs. Like any information source, selective use of evidence can be twisted to support different economic arguments. Thus, the relative lack of randomized clinical trial (RCT) evidence for the efficacy of methotrexate in psoriasis should not imply that methotrexate should not be used or purchased for patients with severe disease

#### Box 2.1 What evidence-based dermatology is not

- Something that ignores patients’ values.
- A promotion of a cookbook approach to medicine.
- An ivory-tower concept that can only be understood and practiced by an exclusive club of aficionados.
- A tool designed solely to cut costs.
- A reason for therapeutic nihilism in the absence of randomized controlled trials.
- The same as guidelines.
- A way of denigrating the value of clinical expertise.
- A restriction on clinical freedom, if this is defined as doing the best for one’s patients.

when there is so much other evidence and long-term clinical experience to support its use. But this is not to say that a clinical trial comparing methotrexate against other systemic agents, such as acitretin or fumarates, would not be desirable at some stage [7]. It was heartening, for example, to see a trial of a biologic for psoriasis compared against methotrexate as an active comparator [8], rather than the usual profusion of placebo-controlled studies that leave doctors confused about which treatment is best.

EBM should not be viewed as a restriction on clinical freedom, if clinical freedom is defined as the opportunity to do the best for your patients, as opposed to making the same mistakes with increasing confidence. Searching for relevant information for your patients frequently opens up *more* rather than fewer treatment options [9]. Shared decision-making through a physician–patient partnership is free to choose or discard the various options in whatever way gives the most desirable outcome.

Guidelines are not the same as EBM, although the two are frequently confused [10]. Guidelines may or may not be evidence based, but guidelines are just that – guidelines. Many dermatology guidelines now incorporate a grading system that describes the quality of evidence used to make recommendations and their strength [11]. Many guideline development groups use methods that combine the strength of available external evidence based on the hierarchy described more fully in Chapter 7 sometimes using specific criteria such as those as recommended by the Grading of Recommendations Assessment, Development and Evaluation working group [12], plus some method for suggesting whether a recommendation is a strong one such as the Strength of Recommendation Taxonomy system suggested by Ebell *et al.* [13]. Striking a balance between only recommending expensive new treatments based on high-quality placebo-controlled clinical trial evidence conducted by the pharmaceutical industry instead of other long-established treatments simply because they pass the “level A” evidence hurdle is a difficult one for guideline developers to get right [14].

## Problems with other sources of evidence

### Working things out on the basis of mechanism and logic

Many physicians base clinical decisions on an understanding of the etiology and pathophysiology of disease and logic [15,16]. This paradigm is problematic, because the accepted hypothesis for the etiology and pathogenesis of disease changes over time, and so the logically deduced treatments change too. For example, in the past 20 years, hypotheses about the etiology of psoriasis have shifted from a disorder of keratinocyte proliferation and homeostasis, to abnormal signaling of cyclic adenosine monophosphate, to aberrant arachidonic acid metabolism, to aberrant vitamin D metabolism, to the current favorite: a T-cell-mediated autoimmune disease. Each of these hypotheses led to logically deduced treatments. The efficacy of many of these treatments has been substantiated by rigorous RCTs, whereas other treatments are used even in the absence of systematically collected observations. We thus have many options for treating patients with severe psoriasis (for example, ultraviolet B, Goeckerman treatment, psoralen-ultraviolet A, methotrexate, ciclosporin, and at least six biologics) and mild to moderate psoriasis (for example, dithranol, topical corticosteroids, calcipotriol, and tazarotene). However, we do not know which is best, in what order they should be used, or in what combinations.

Treatments based on logical deduction from pathophysiology can have unexpected consequences. For example, the observation

that antiarrhythmic drugs could prevent abnormal ventricular depolarization after myocardial infarction logically led to their use to prevent sudden death after myocardial infarction. However, RCTs showed increased mortality in patients treated with antiarrhythmic drugs in comparison with placebo [17,18]. So, although patients' electrocardiograms looked a lot happier and smoother, more people died whilst on treatment. This example highlights the dangers of using surrogate outcome measures, such as electrocardiograms, for more meaningful outcomes, such as disability or death, simply because the surrogate measurements are easily made. The challenge with surrogate outcome measures is to ensure that they measure important things rather than trying to make measurable things important. Another classic example of the dangers in basing our treatments on empirical observations of “scientific” mechanisms is the clinical trial of thalidomide for toxic epidermal necrolysis (TEN) [19]. On the basis of observations that TEN is associated with high levels of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), a trial of thalidomide (a drug that inhibits the actions of TNF- $\alpha$ ) was commenced. The trial was stopped early because 10 out of 12 patients in the thalidomide group died, in comparison with three of 10 on placebo treatment. It was also found that those in the thalidomide group had an unexpected increase in TNF- $\alpha$  levels during treatment.

Some “designer” drugs, such as topical tazarotene, were promoted on the basis of their molecular mechanisms of action and may have appeared attractive at launch, but have been less exciting when tested in practice [5]. It might also be argued that the frequent narration of the superantigen story as a mechanism for antistaphylococcal treatments for atopic eczema is a smokescreen that obscures the real lack or uncertainty of evidence of clear benefit for such agents [20].

Given these lessons, many dermatologists have become less interested in *how* treatments work and are now daring to ask questions such as: “Does it work?” and – more important than a demonstration of statistically significant efficacy in comparison with placebo – “How *well* does it work in comparison with existing, more established treatments?”

### Personal experience

Although personal experience is an invaluable part of becoming a competent physician, the pitfalls of relying too heavily on personal experience have been widely documented [21–23]. These include:

- overemphasis on vivid, anecdotal occurrences and underemphasis on statistically significant strong evidence;
- bias in recognizing, remembering, and recalling evidence that supports preexisting knowledge structures (for example, ideas about disease etiology and pathogenesis) and parallel failure to recognize, remember, and recall evidence that is more valid but does not fit preexisting knowledge or beliefs;
- failure to characterize population data accurately because of ignorance of statistical principles – including sample size, sample selection bias, and regression to the mean;
- inability to detect and distinguish statistical association and causality;
- persistence of beliefs despite overwhelming contrary evidence [23].

Nisbett and Ross [24] provide examples of these pitfalls from controlled clinical research, and simple clinical examples abound. Physicians may remember patients assuming that those who did not return for follow-up improved, and conveniently forget the patients who did not improve. A patient treated with a given medi-

cation may develop a severe life-threatening reaction. On the basis of this single undesirable experience, the physician may avoid using that medication for many future patients, even though on average it may be more efficacious and less toxic than the alternative treatments that the physician chooses. Few physicians keep adequate, easily retrievable records to codify the results of treatments with a particular agent or of a particular disease, and even fewer actually carry out analyses. Few physicians make provisions for tracking those patients who are lost to follow-up. Thus, statements made about a physician's "clinical experience" may be biased. Finally, for many conditions, a single physician sees far too few patients to draw reasonably firm conclusions about the response to treatments. For example, suppose a physician who treated 20 patients with lichen planus with tretinoin found that 12 (60%) had an excellent response. The confidence interval for this response rate (i.e., the true response rate for this treatment in the larger population from which this physician's sample was obtained) ranges from 36% to 81%. Thus, the true response rate might well be substantially less (or more) than the physician concludes from personal experience [15,25]. Personal experience alone is also unlikely to pick up smaller treatment differences between active treatments. A new treatment must be substantially better than an existing treatment for a physician to notice. If, in the above example of lichen planus, standard treatment with topical corticosteroids resulted in a response rate of 55%, then the physician would need to treat 20 patients on average (number needed to treat equals the reciprocal of 60% minus 50%) to notice one additional success from tretinoin.

### Expert opinion

Expert opinion can be valuable, particularly for rare conditions in which the expert has the most experience or when other forms of evidence are not available. However, several studies have demonstrated that expert opinion often lags significantly behind conclusive evidence [21]. Experts suffer from relying on bench research, pathophysiology, and treatments based on logical deduction from pathophysiology, and from the same pitfalls noted for relying on personal experience [25]. Some have even questioned the value of content experts when producing systematic reviews of evidence [26].

Textbooks can be valuable, particularly for rare conditions and for conditions for which the evidence does not change rapidly over time. However, textbooks have several well-documented shortcomings. They tend to reflect the biases and shortcomings of the experts who write them. By virtue of the way in which they are written, produced, and distributed, most are at least 2 years out of date at the time of publication. Also, many textbook chapters are narrative reviews that do not consider the quality of the evidence reported [21,25,27].

### Uncontrolled data

Empirical, uncontrolled and unsystematically collected data form the basis of much of dermatology practice. This situation is justified by its advocates by two erroneous assumptions. The first is that it is acceptable to use such data because better evidence is not available – an assumption that is often not true due to lack of training in searching for relevant information, as discussed in Chapter 6. There is a surprisingly large body of high-quality evidence that is useful for the care of patients with skin disease, as exemplified by the growing body of evidence-based treatments discussed in this book and by the exponential increase in systematic reviews of skin treatments [28]. The second erroneous assumption is that the

majority of dermatologists already base their practice on the best evidence that is already available. The base of knowledge for the practice of medicine is expanding exponentially. It is estimated that, to keep up with the best evidence available, a general physician would have to examine 19 articles a day, 365 days a year [2]. Therefore, keeping up to date by reading the primary literature is now an impossible task for most practicing physicians [29]. The burden for dermatologists is no less daunting [5]. The challenge is to know how to find information efficiently, appraise it critically, and use it well. Knowing the best sources and methods for searching the literature allows a dermatologist to find the most current and most useful information in the most efficient manner, when it is needed. The techniques and skills needed to find, critically appraise, and use the best evidence available for the care of individual patients have been developed over two centuries. These techniques and skills are currently best known as EBM [2,15].

## The process of evidence-based dermatology

Having discussed the definition and rationale of EBD, how does one actually do it? This process is best considered in five steps (Box 2.2), although in real life they tend to merge and become iterative [5]. These steps are elaborated in subsequent chapters.

### Step 1: asking an answerable structured question

Developing a structured question that can be answered requires practice. An example of a useless question would be, "Are diets any good in eczema?" A better question, generated from a real clinical encounter, would be, "In children with established moderate to severe atopic dermatitis, how effective is a dairy-free diet in comparison with standard treatment in inducing and maintaining a remission?" Such a question includes four key elements:

- the patient population to which one wishes to generalize;
- the intervention;
- its comparator;
- the outcomes of interest and their timing that might make you change your practice [30].

Unless one uses such a PICO (patients, intervention, comparator and outcome) structure, it would be easy to waste time discussing and searching for data on the role of diets in preventing atopic disease, the effects of dietary supplements such as fish oil, studies that evaluate only short-term clinical signs, and those that deal with a "ragbag" of different types of eczema in adults and children. Bigby and Rzany discuss further examples of framing answerable questions in more detail in Chapter 5.

### Step 2: searching for the best external information

Publication of biomedical information has now expanded so much that it is hard to contemplate searching for relevant information without some form of electronic bibliographic search, followed by reading the original key papers. Most of us (including the authors)

#### Box 2.2 The five steps of practicing evidence-based dermatology

- 1 Asking an answerable structured question generated from a patient encounter.
- 2 Searching for valid external evidence.
- 3 Critically appraising that evidence for relevance and validity.
- 4 Applying the results of that appraisal of evidence back to the patient.
- 5 Recording the information for the future.

are not experts at performing complex electronic searches, and need to learn such skills. These skills are dealt with in more detail by Bigby and Corona in Chapter 6. As pointed out earlier, traditional expert reviews are risky, because often they have not been done systematically, and the links between the author's conclusions and the data are often unclear [31]. Thankfully, many systematic reviews have now been done in dermatology, and those that have been done in atopic dermatitis and acne have been mapped in a publically accessible resource at the Centre of Evidence-Based Dermatology (<http://www.nottingham.ac.uk/scs/divisions/evidencebaseddermatology/resources/index.aspx>). In the absence of good-quality systematic reviews, then, one often ends up searching for individual randomized controlled trials. Searching for trials on the Medline and Embase databases is hazardous unless one is proficient, because simply searching by the "clinical trials" type can miss up to half of the relevant trials due to coding problems [32]. The world's most comprehensive database of clinical trials is now the Cochrane Central Register of Controlled Clinical Trials (CENTRAL) which can be found at <http://www.thecochranelibrary.com> and which contained 680 109 records in September 2012. Thankfully, it is also the easiest to search.

### Step 3: sifting information for relevance and quality

The usefulness of an article is a product of its clinical relevance, multiplied by its validity, divided by its accessibility [33]. Information sources need to be near the clinical area if they are to be used for patients. Becoming distracted by irrelevant but interesting citations is also a real hazard when reading search results. Two filters need to be applied if one is to keep practicing EBD: the first is to discard irrelevant information, and the second is to spend more time looking at a few high-quality papers. It is timely at this point to mention the concept of the hierarchy of evidence [34], which is discussed in more detail in Chapter 7. This means that if a randomized controlled trial is found that deals with the question of interest (for example, dietary exclusion in childhood atopic dermatitis), or better still a systematic review dealing with the same topic, one should critically appraise these sources rather than dilute what little time one has by reading lots of case series and case reports.

### Step 4: applying the evidence back to the patient

This is usually the most important step, although the least well developed in EBD. Key points to note here are:

- to consider how similar the patients in the studies are to the patient facing you now;
- whether the outcome measures used in those studies are clinically meaningful for both you as a practicing doctor and the patient;
- how large the treatment benefits were;
- what the drawbacks of the intervention were;
- how the evidence fits in with your patient's past experience and current preferences.

This difficult area is discussed in more detail in Chapter 18.

### Step 5: recording the information for the future

Having done so much work pursuing the above "evidence-based prescription" from question to patient, it might be useful to others and yourself to make a record of that information for future use as a critically appraised topic (CAT), although this has a limited

lifespan if not updated [2]. Such CATs could become the norm in dermatology journal clubs all over the world, replacing unstructured chats about articles selected for unclear reasons. Some dermatology journals have promoted the use of CATs as an educational tool [35,36].

The key point to remember about the process of EBD is that it *starts and ends with patients*. A problem highlighted during an encounter with a patient is the best generator of an EBM problem [37]. Even if one then searches and critically appraises the best data in the world, the utility of this exercise would be zero if it were not then applied back to that patient or other similar patients. Developing the skills to undertake evidence-based prescription requires practice.

Dermatologists will participate in the practice of EBD to different degrees depending on their enthusiasm, skills, time pressures, and interest [34]. Some will be "doers," implying that they undertake at least steps 1–4 highlighted in Box 2.2. Others will be more inclined to adopt a "using mode," relying on searching for secondary evidence sources such as evidence-based summaries – for example, systematic reviews that others have constructed – thereby skipping step 3, at least to some degree. Finally, some will incorporate evidence into their practice in a "replicating mode," following decisions of respected leaders (i.e., skipping steps 2 and 3). These categories bear some similarity to those of deduction, induction, and seduction that Sackett used to describe the methods that physicians employ to make decisions about therapy [21]. Such categories are not mutually exclusive, since even the most enthusiastic EBM practitioners in "doing" mode will flit to "user" and "replicating" mode according to whether they are dealing with a common or rare clinical problem.

## Conclusions

Few dermatologists would argue that their overarching professional role is to provide their patients with the best health care. To do so, a dermatologist must be able to assess the patient's physical condition, know the best and most current information about diagnosis, prevention, therapy, prognosis, and potential harm, and then apply that knowledge of universals to the individual patients [38,39]. Medicine is advancing very rapidly, creating major changes in the way we treat our patients. It is imperative that we, as health-care professionals, keep up with such changes. We need to be up to date with such new external evidence. We frequently fail to do this if we rely on passive means or an occasional flick through the main journals, and our knowledge gradually deteriorates with time. Attempts to overcome this deficiency by attending clinical education programs fail to improve our performance, whereas the practice of EBM has been shown to keep its practitioners up to date. EBM is a way of thinking that is intended to help accomplish these objectives. If we stick to thinking about *patients' welfare* when contemplating EBM, we are less likely to get things wrong [5,15].

## CHAPTER 3

# The role of patient and public involvement in evidence-based dermatology

Carron Layfield, Amanda Roberts, Jason Simons, Colette O'Sullivan, Anjna Rani, and Kim Thomas

Centre of Evidence Based Dermatology, University of Nottingham, Nottingham, UK

### Introduction

Various terms are used to describe patients, carers, and members of the public involved in health care, particularly with regard to research. The term patient and public involvement (PPI) is now widely used, and we use it here. PPI means health professionals, patients, carers, and the public working together to improve the health of the communities they represent.

Compelling evidence shows that patients who take an active part in managing their own health care have better outcomes than those who are passive recipients. Increasingly, patients are active, informed people who want to know more about their condition and have more control over their own care. Education can help patients share responsibility for their own care. They also need access to trustworthy information to make important choices about their treatment. Easy access to relevant, evidence-based information will help them to choose the care they need and want.

Those involved in PPI in evidence-based dermatology are bringing their experience and perspective to the table. Their participation in activities such as the prioritization of research projects, through to proof reading of articles for public consumption will help to ensure that any work done is of interest and of use to all end users.

### The many benefits and roles of patient and public involvement in health care

PPI can bring many benefits to health care, not least having better informed patients and carers as outlined above. Other benefits include improving the quality of health care and making better use of existing resources; this includes improving access to services and making monitoring and evaluation of services more effective.

The roles of PPI in health care are many and varied and are outlined below (several are discussed in more detail later):

- playing an active part in self care as far as possible;
- working with professionals to improve one's own care and that of other family members and those in the general community;
- to share personal experiences of living with a disease and to inform and educate other patients and professionals;
- assisting with the development and governance of health institutions and organizations;

- contributing to research policy and practice by helping to decide research priorities and funding and helping to improve the design of research;
- to support the recruitment of patients into research studies;
- helping to disseminate important research findings.

Such PPI can benefit all those involved in the health-care process in different ways. For example, patients will benefit from seeing their views considered and used to improve the quality of care for others, while health service managers will benefit from improved standards of more patient-friendly services. Health service researchers can benefit greatly, as working with patients, carers, and the public from the very start of their projects can much improve the quality of their research design and outputs.

### The skin shows: it matters psychologically and socially

The roles of PPI in health care are generic across all clinical specialties. Skin diseases differ from other illnesses in being much more visible, whether through constant itching, visible patches on the skin, or flaking of the skin. In this crucial area, patients and carers can help professionals understand and learn what matters to people with various skin conditions; those unaffected may find these aspects difficult to understand and recognize appropriately.

Many people with skin disease experience significant psychological and social distress such as depression and fear of stigma [1]. A recent German study of patients with occupational hand eczema found a high prevalence of anxiety and depression among them [2]. Although recognized, this has rarely been addressed when considering treatment options, and a survey [3], conducted for the European Commission on public opinions, found that the patients they surveyed felt "doctors do not take account of the 'psychological' impact of treatments and their effects in day-to-day life."

The extent of disease may not be the most important factor in considering a patient's suffering. Self-esteem, self-image, the site of the lesions, how far the patient feels disabled, and the support networks available should all be considered. For example, an office worker may tolerate extensive psoriasis on covered areas of the body, but as soon as the psoriasis starts to affect "high expression" and visible areas, such as the face and hands, quality of life can drop drastically. More could be done to ensure that practitioners assess

the impact of psychosocial issues, and that treatment provided is just one part of the holistic management of skin disease. A study of core beliefs and psychological distress in patients with psoriasis and atopic eczema attending secondary care identified a potential link between early maladaptive schemas (vulnerability to harm and defectiveness) and anxiety, social isolation and depression [4]. Such findings have clinical implications for the psychological management of such patients. Although a Cochrane review of psychological and educational interventions for atopic eczema in children found little research in the area, relaxation methods appeared to reduce the severity of childhood eczema, as did several health education programs for the families of affected children [5]. Skin camouflage is an important treatment option for certain skin diseases (e.g., vitiligo). The British Association of Skin Camouflage (<http://www.skin-camouflage.net/>) provides advice on skin camouflage and states, “The psychological benefit to people who have been shown how to successfully apply and manage skin camouflage cannot be over-emphasised . . . it empowers them to face the world, with confidence!”

## Education and information for self-care

### The role of patient support groups

Treatment of a skin disorder involves more than a professional diagnosis, the use of medication (prescription or over-the-counter remedies), or even care in hospital. Those affected may seek advice from a clinician but also rely on support from family members, friends, and fellow patients to help manage their condition. Many will seek further information outside the clinical community to educate themselves about the management of their skin disease, and patient support groups (PSGs) can be an excellent resource for this.

PSGs provide a setting in which people who share similar experiences come together to offer reciprocal and mutually helpful practical and emotional support. People go to a PSG for many different reasons; some simply want information and will then move on. Others may want to make sense of what is happening to them by sharing with those who have been through something similar. Often, advice from a PSG can resolve practical everyday problems that clinicians are not aware of or avoid dealing with due to embarrassment or a lack of understanding. Dermatology PSGs and advocacy groups are increasingly being recognized as important in health policy, patient education, national guideline committees, and research [6].

The British Association of Dermatologists’ website (<http://www.bad.org.uk/site/575/default.aspx>) [] lists over 60 PSGs in the UK for both common and rare skin conditions. The groups are generally run by patients or non-health-professionals, often volunteers. Many have been founded by patients and/or carers affected by the condition concerned who have been frustrated by the lack of available information. PSGs support patients living with their diagnosis through information leaflets (often produced together with professionals), newsletters, confidential phone lines, personal email responses, and information on websites. Leaflets and information sheets are often tailored to specific groups (e.g., children, parents, teachers, general public), but groups also often give health professionals valuable information. PSGs are found across the globe; for example, in Canada, The Canadian Skin Patient Alliance is an overarching nonprofit organization providing education, information, a supportive on-line community, and opportunities to create and join local support groups for people with skin disease (<http://www.skinpatientalliance.ca>).

Such information is essential for patients. A person living with a long-term condition spends on average 3 h per year with a clinician; the rest of the time they are in charge of their own care [7]. Informing and educating patients and carers, helping them interpret research evidence, and correcting misconceptions can help with improved self-care and shared decision-making [8]. In this way, PPI can thus help not only patients and carers but also health providers, since self-care at home can reduce attendance at specialist clinics.

### The rise of internet and social networking

Skin conditions can limit the opportunities that patients or carers have to interact in the outside world – for example fewer mothers of children with atopic eczema have an outside job [9]. The virtual world can enable the person to reach out to address their concerns at a time to suit them. Dermatology patients may seek more internet advice than patients affected by other disorders; the reasons include frustration with explanations received from professionals, feelings of helplessness, desire for anonymity, coping with feeling ill-informed, and seeking information for another [10].

As noted, most PSGs have website and contact emails, but in the past few years much more has been added. Social networking includes news, blogs, podcasts, virtual communities, twitter, wikipedia, videos, mobile phone apps, and other things like photo sharing through web-based technologies. Not only PSGs offer relevant information; third-sector, government, and pharmaceutical organisations all have resources for the patient, carer, and the health professional. It is perhaps worth mentioning that not all websites that appear to provide neutral medical information are in fact doing so. Some are funded by for-profit companies wishing to highlight their products, so it is worth looking carefully at who is running and funding the information being provided. Different search engines generate different results, sending the user to different sites [11]. Social networking allows contact with like-minded people both nationally and internationally. Each different web-based medium gives different opportunities to interact with people concerned with dermatology, potentially promoting health literacy, which should strengthen patient engagement [12].

Excellent examples of websites showing patients’ experiences are Healthtalkonline (<http://www.healthtalkonline.org>) and the sister website Youthhealthtalk (<http://www.youthhealthtalk.org>). Here, one can share in over 2000 peoples’ experiences of over 70 health-related conditions and illnesses. Unfortunately it doesn’t yet include experiences of skin disease, but Youthhealthtalk sections on acne, psoriasis, alopecia and eczema in young people are planned for 2015/16 (available at: [www.Youthhealthtalk.org](http://www.Youthhealthtalk.org)). A section on participating in clinical research may be of general interest.

It has been shown that a great deal of medical information on the web is wrong [13], due to carelessness, misinterpretation, misrepresentation, or inappropriateness. While primary care physicians seem more likely to seek answers to clinical questions from colleagues than from electronic sources [14], less is known about patients’ hierarchy of information. The acquisition of poor-quality information alone may not empower patients to share decision making [15] and may even result in “cyberchondria.”

Individual voices can blur boundaries. Health professionals, patients, and carers can connect and participate in real-time topical discussions (for example, thorough Twitter). But individual voices can be persuasive and misleading – it is generally unwise to rely on other people’s stories as a guide to how likely you are to experience similar benefits or harms from an intervention.

## Patient and public involvement in the research process

There are many opportunities for PPI in research, including assisting with Cochrane systematic reviews, helping to identify research priorities, peer reviewing applications and proposals, commenting on patient-relevant outcomes in research, helping to develop study documents, and the dissemination of research results. In health research, PPI is crucial as it helps to ensure that the research undertaken is useful and relevant to patients [16]. In the UK, INVOLVE (<http://www.invo.org.uk>) was established in 1996 and is now part of, and funded by, the National Institute for Health Research (NIHR), to support active public involvement in National Health Service, public health, and social care research. It aims to bring together expertise, insight, and experience in the field of public involvement in research, to advance PPI as an essential part of the research process. INVOLVE is one of the few government-funded programs of its kind in the world and is an excellent starting point for finding out more about the role of PPI in research.

An example of PPI in dermatology research has been the establishment with NIHR funding of a Patient Panel in 2009 by the Centre of Evidence Based Dermatology at the University of Nottingham, UK (<http://www.nottingham.ac.uk/dermatology>). It aims to create a more effective research environment and to give more support for those wanting to get involved in dermatology research by holding regular training events. The panel has over 20 active members involved in a wide range of research activities.

## The role of patient support groups

As well as providing information and advice, many dermatology PSGs further support PPI by directly funding research, supporting participation in research, or both. In the UK, the sums awarded by dermatology PSGs for research funding are modest compared with other disease areas. Over the past 40 years the Psoriasis Association (<http://www.psoriasis-association.org.uk>) has awarded over £4 million in research funding and is now focusing on funding the next generation of researchers through PhD projects. DEBRA (<http://www.debra.org.uk>), the UK charity working on behalf of people with the genetic skin blistering condition epidermolysis bullosa, funds research into the possible causes and treatments of the disease. In addition, the umbrella group DEBRA International (<http://www.debra-international.org>) helps to coordinate the research activities of over 30 member organisations across the world. In the USA, the National Eczema Association (<http://www.nationaleczema.org>) gives small grants for patient-orientated eczema research. These focus on topics of primary importance to the patients and their families: itch, infection, prevention, skin-barrier function, and psychosocial aspects of the disease.

A number of PSGs promote research studies on their websites and in newsletters to help raise the profile of such studies to potential participants in addition to helping to disseminate research results. In the UK, the National Eczema Society (<http://www.eczema.org>) and the Vitiligo Society (<http://www.vitigosociety.org.uk>) were partners in the priority setting partnerships outlined below which helped identify the top clinical research priorities for these disorders.

## Cochrane systematic reviews

The Cochrane Collaboration (<http://www.cochrane.org>) actively promotes PPI in its work, and the Cochrane Consumer Network (CCNet) was set up in 1995 to help manage this aspect (<http://consumers.cochrane.org>). The Cochrane Collaboration is divided

into Cochrane review groups responsible for particular disease areas. The Cochrane Collaboration strongly encourages PPI in their protocols and reviews, and many groups liaise with CCNet to do this.

A patient and carer perspective on systematic reviews is important. Most lead review authors are health professionals and consider a question for a review because of their own experiences in a clinical environment or through health-care research. The purpose of PPI input during the review process is to:

- ensure that a review question is relevant to people requiring health care;
- identify outcomes from health-care interventions that matter to patients – these may differ from those identified by service providers;
- improve access to reviews by ensuring that the review can be read and understood by a wide audience and that language is sensitive to patients, carers, and the public;
- weigh the benefits of a health-care intervention against the potential harms – only patients can say which issues matter most to themselves and their families or carers;
- help decide priorities for new reviews.

Members of CCNet are individuals as well as community-based organizations from across the world. CCNet supports and trains its members, encouraging them to join in the work of the collaboration. It works to keep consumers informed, develops training materials, helps demystify scientific jargon to make reviews more accessible to the public, and publishes a digest of new additions to the Cochrane Library, including full lay summaries of reviews. The CCNet website is a means of commenting on issues and reviews and links to other sources of evidence-based health care. In addition, some groups like the Cochrane Skin Group (<http://skin.cochrane.org>) have set up their own list of consumers who have previously commented or have expressed an interest in a particular area. An outstanding example of PPI in Cochrane Skin Group reviews can be found in the treatments for vitiligo review and update, led by a vitiligo patient, Maxine Whitton [17].

## Priority setting partnerships

Priority setting partnerships bring patients, carers, and health professionals together with the aim of identifying shared priorities for research on specific health problems. In the UK, this is facilitated by the James Lind Alliance (JLA) which supports and guides the priority setting partnership as a neutral facilitator (<http://www.lindalliance.org>). The aim is to agree by consensus on a top 10 list of uncertainties for future research. This approach leads to priorities that reflect both clinical and patient perspectives and, therefore, should yield the greatest improvements in health care. An online guidebook (<http://www.jlaguidebook.org>) helps those who wish to carry out a priority setting partnership. These questions are then published in the Database of Uncertainties about the Effects of Treatments (DUETs, <http://www.library.nhs.uk/duets>) to prompt research funders and commissioners. Priority setting partnerships have been working on a variety of disorders, including asthma, type 1 diabetes, and schizophrenia. To date, two partnerships have worked in dermatology: one on vitiligo [18] and one on eczema treatments.

## Vitiligo Priority Setting Partnership

A recently updated Cochrane systematic review “Interventions for vitiligo” showed that the research evidence for the treatment of vitiligo was poor, making it difficult to make firm recommendations

for practice [17]. The Vitiligo Priority Setting Partnership was established and included patients, representatives from the Vitiligo Society, health professionals, and researchers. It worked with guidance from the JLA as outlined above with the aim of finding out why there was so little high quality research on the treatment of vitiligo. The priority setting partnership worked in three phases: a survey to collect the treatment uncertainties from patients and health professionals; a ranking exercise in which participants were asked to vote for their favorite topics from a list of the most frequently asked uncertainties; and finally, a workshop at which the most popular treatment uncertainties were developed into research questions [18].

The final list of the top 10 treatment uncertainties included interventions such as systemic immunosuppressants, topical treatments, light therapy, and the impact of psychological interventions on the quality of life of patients with vitiligo. Five research vignettes based on these top 10 uncertainties were submitted to the NIHR Health Technology Assessment Programme, which has since called for a randomized controlled trial of the use of UVB light combined with topical corticosteroid for the treatment of vitiligo.

### **Eczema treatments priority setting partnership**

Though much research has been done on eczema, no explicit attempt had been made to identify the treatment uncertainties in eczema that matter to patients, their carers, and the professionals treating them. A priority setting partnership for eczema treatments did this. As with the Vitiligo Priority Setting Partnership, the Eczema Priority Setting Partnership worked in three phases. The final workshop used the ranked uncertainties, current evidence, and personal/professional experience to develop research questions about eczema treatments which will be published, publicized, and used to guide future research as was done for vitiligo.

### **Clinical trials: development, delivery, and dissemination**

PPI is crucial not only to the design and conduct of a clinical trial but also to the dissemination of study results. Although currently recognized as being important, a recent study by the Medical Research Council (MRC) revealed that between 1989 and 2009 only 31% of MRC funded trials had some form of PPI [19]. In the UK it is important to remember that now many funders of clinical research, including NIHR funding bodies, will only fund applications that demonstrate meaningful PPI throughout the planned study.

### **Patient and public involvement in clinical trial development**

Involving patients and carers from the early stages of the research development process helps ensure that the question posed by the study is relevant to those who would be involved. This should help recruitment into the trial, as patients will be more interested in taking part. Such input can make sure that the number, timing, and duration of visits required for a study are acceptable to patients and carers, along with the treatments/interventions planned. In addition, PPI can help identify study outcomes important to patients which the professionals may not have considered. This is well demonstrated by the STOP GAP study of pyoderma gangrenosum, where, after focus groups and structured interviews with patients, pain control was given greater prominence as an outcome measure for the trial [20]. Further involvement in the design and wording of relevant study materials, such as patient information sheets and

diaries, will make sure that such documents are clear and easy to understand.

### **Patient and public involvement in clinical trial performance**

An obvious role for PPI in the performance of clinical trials is for patient representation on a trial steering or management committee to see that the needs of the study participants are being considered throughout the duration of the trial. People can also be involved by using previous study participants to act as patient advocates, encouraging their engagement to take part in a trial. PSGs can help recruitment by advertising on their websites and social networking. The Dermatological Sciences Research Group at the University of Manchester, UK, has a significant online presence to boost recruitment strategies. It uses Facebook (<https://www.facebook.com/pages/Manchester-Skin-Research/197339573612685>) and Twitter (@McrSkinResearch) to highlight studies that are actively recruiting and to keep participants and potential participants informed on their progress and their research.

### **Patient and public involvement in disseminating clinical trial results**

Results from clinical research are published in scientific and medical journals that mostly do not reach the public and are hard for lay readers to understand. This can make the results of clinical research inaccessible for the very people they aim to benefit. The purpose of PPI in helping to disseminate research results is to give advice as to how and when research results should be disseminated, to help widen the audience for the dissemination of clinical research results, and to identify existing research that is not currently being disseminated or implemented. This can be done not only by helping to draft accessible reports and lay summaries of research findings, but also by suggesting different ways in which research results can be presented and distributed so that they are accessible to people of all age ranges and hard-to-reach groups (e.g., podcasts and video clips). Becoming an advocate of research in the patient community and communicating results via relevant PSG websites and social networking groups is becoming an important way of disseminating study results to patients, carers, and the public.

### **Summary**

Given that many skin conditions are chronic, a high proportion of patients and their carers want to know as much as possible about their skin disease; not only the causes and prognosis for their disorder, but also the costs and benefits of the many treatment options available to them. Health professionals, patients, and carers have many opportunities to work together to benefit the field of evidence-based dermatology, and PPI is increasingly recognized as a vital component of successful skin research.

Patients and carers are often in the best position to guide researchers and health professionals on what matters to them most in terms of therapeutic benefit and can give psychological support and useful information to fellow patients and carers in ways that doctors cannot. They are well placed to help prioritize relevant dermatology research by framing research questions that are the most important to them and by helping researchers choose meaningful outcome measures for such studies. PSGs should not be ignored in research; they are ideally positioned to help boost recruitment by advertising studies, assist with the dissemination of study results, and, of course, fund research projects.

## Acknowledgments

We wish to thank Maxine Whitton and Andrew Herxheimer, the authors of this chapter in the second edition, for help with this update.

## CHAPTER 4

# The Cochrane Skin Group

Finola Delamere, Liz Doney, Laura Prescott, and Shirley Manknell

Cochrane Skin Group, Centre of Evidence Based Dermatology, University of Nottingham, Nottingham, UK

### Background

The Cochrane Collaboration developed in response to a challenge issued by Archie Cochrane (1909–1988), a British epidemiologist, who in 1972 pointed out the deficiencies of reviews of the medical literature and the lack of access to up-to-date information about health care [1]. In response to his criticism about the great ignorance of the effects of health care, the international organization The Cochrane Collaboration was set up in 1993 at a meeting of 77 people from 11 countries, after the first Cochrane Centre had opened in 1992.

Archie Cochrane wrote [2]:

It is surely a great criticism of our profession that we have not organized a critical summary, by specialty or subspecialty, adapted periodically, of all relevant randomized controlled trials.

The Cochrane Collaboration aims to facilitate systematic assessment of the available evidence from clinical trials in the form of systematic reviews, for the benefit of both health professionals and the general public. Reviews are now published in *The Cochrane Library* (<http://www.thecochranelibrary.com/>) electronically via a website. This is free to access for many people through a national provision license, such as is provided by the British National Health Service (NHS) and in low-income and middle-income countries through various initiatives to allow access (<http://www.thecochranelibrary.com/view/0/FreeAccess.html>).

The year 2014 is The Cochrane Collaboration's 22nd year. It has grown to be an organization in which more than 31 000 people from over 120 countries contribute, but the 10 guiding principles of The Cochrane Collaboration remain unchanged:

- collaboration
- building on the enthusiasm of individuals
- avoiding duplication
- minimizing bias
- keeping up to date
- striving for relevance
- promoting access

- ensuring quality
- continuity
- enabling wide participation.

### The Cochrane Skin Group

The Cochrane Skin Group (CSG) is a network of people from all over the world committed to producing and updating systematic reviews of trials relating to skin conditions. Members of the CSG are linked together by us at the editorial base, and we are keen to harness the energy and expertise of individuals whether they are from a clinical, scientific, or lay background. From the very beginning, consumer involvement has been prominent, and the CSG has become truly international and multi-disciplinary. Over 600 CSG authors are now supported worldwide.

The CSG editorial base was registered as a Cochrane entity in December 1997, and it is one of the 53 review groups that make up The Cochrane Collaboration. The founder, Professor Hywel Williams, is the coordinating editor of the group, which has its editorial base at the University of Nottingham, UK.

In addition to the coordinating editor, the editorial base also includes a managing editor, a trials search coordinator, and an editorial assistant. The CSG is supported by 10 key editors, 2 statistical editors, 2 methodological editors, and a feedback editor. The details and contact information for these editors can be found on the CSG website (<http://skin.cochrane.org/contact-editorial-team>).

Infrastructure support for the editorial base comes from the National Health Service Research & Development Programme, in the form of a National Institute for Health Research (NIHR) Cochrane Review Group Infrastructure Award, which runs for 5 years until 2015. The group accepts no funding from pharmaceutical companies. All our editors publicly declare their interests on our website.

Our systematic reviews benefit dermatology by providing the evidence on which dermatologists and other health professionals can base their clinical decisions, and by helping people with skin diseases become more informed about their health care.

Traditionally, Cochrane systematic reviews have differed from other systematic reviews in important ways: the authors have openly declared their intentions in the form of a peer-reviewed published protocol; the review has been written by several people, each bringing a unique contribution to the team; the search for randomized controlled trials (RCTs) has been wide (i.e., it has not been confined to one or two databases), and the author team has pledged to update the review regularly so that it is always providing the best available evidence for health care.

The quality of Cochrane reviews depends on whether the authors have drawn their conclusions from a valid assessment of the studies they have included in their review. They do this by assessing the biases of each study using The Cochrane Collaboration's "Risk of bias" tool, which is described in the *Cochrane Handbook for Systematic Reviews of Interventions* [3]. Working at the editorial base we get great satisfaction from helping authors produce quality reviews. To that end we welcome the recent introduction of the Methodological Expectations of Cochrane Intervention Reviews document, which gives the standards to which we should all adhere for the conduct and reporting of new Cochrane reviews.

Being part of a Cochrane review can be a challenging but also a great learning experience for all involved; most authors are volunteers. Some author teams have great fun and form lasting friendships both with each other and us back at the editorial office. Also, leading a review team may have definite career benefits. Public authorities in some countries give grants for particularly important topics to pay a member of the review team for time dedicated to the review.

### Types of Cochrane reviews

The Cochrane Collaboration has traditionally produced "intervention" reviews which assess RCTs addressing a particular clinical question. However, it is recognized that RCTs are not always appropriate for answering some questions, and so non-randomized studies may have to be included. As these studies tend to be more biased, the means to deal with them must be specified in the protocol. In recent years, diagnostic test accuracy reviews have been published; the CSG is now preparing a protocol for such a review. Cochrane overviews are those which bring together a number of small intervention reviews rather than the primary studies. The CSG generally aims to write large "all-encompassing" reviews of primary studies because we think these are of more use to the practitioner and to the person who has the particular skin condition; therefore, we have less need to write "overviews of reviews." Finally, Cochrane methodology reviews address methodological issues.

### Scope of the Cochrane Skin Group

Around 1000 skin diseases are described in the Topic List on our website [4]. These are based on the British Association of Dermatologists' diagnostic index and are used to classify our reviews. As well as standard medications and interventions for skin diseases, we also include cosmetic skin care products, alternative or complementary treatments, and medications that may be prescription drugs in one country and over-the-counter preparations in another. There is inevitably overlap with other Cochrane Groups, particularly with Wounds, Sexually Transmitted Infections, Pain and Palliative Care, and Infectious Diseases, so those with an interest in dermatology should also look for relevant reviews produced by other groups.

## Editorial process: join the Cochrane Skin Group and publish a high-impact paper!

For those keen to contribute to the development of a CSG systematic review, the process begins with individuals getting together with an important clinical question, which they may have suggested themselves or seen advertised on the CSG's website [5]. The team of authors on a review will ideally include a lead author who will assign tasks to the team and ensure they keep to the time-lines for completion; this person will of necessity devote much of their time to the review and will need at least one other person on the team to commit time to independent data extraction and generally to help complete the review. The other team members may not need to commit so much of their time, but will include:

- an experienced Cochrane author who can guide the team in the process;
- a clinician who is an authority on the subject of the review;
- a methodologist or statistician who will guide the team in understanding the results and doing the analyses; and
- a consumer who will aim to ensure the review is understood by the intelligent layman, that it adequately reflects the experience and social impact of the disease on the individual and family, and addresses outcomes in a way that is important to a person with the skin condition or caring for someone with that skin condition.

As Cochrane reviews are published in English, we ask that someone on the team has a good command of written English. Once the team of authors is formed, a title has to be registered. When it is accepted the authors are officially given access to the title through the Cochrane Information Management System, known as "Archie." First, the team must publish a protocol: the plan for the review. This will include a background section, a search strategy, and the planned methods for study selection, data extraction, and analysis.

Within 2.5 years of title registration, a review should be completed and published. The main stages of writing a Cochrane review are that:

- 1 a full and systematic search is undertaken;
- 2 relevant papers and other information are gathered;
- 3 two authors independently decide which papers meet the inclusion criteria;
- 4 these papers are then evaluated in a "Risk of bias" assessment;
- 5 the data are extracted and critically analyzed – with a meta-analysis if appropriate; and
- 6 the data are summarized and conclusions drawn in a way that health practitioners, managers, and consumers can understand.

Authors are expected to update their reviews at least every 2 years.

Each review is prepared in a defined manner to ensure consistency and high quality, using The Cochrane Collaboration's own free software, "Review Manager." Both the protocol and review undergo peer review by an editor, an external content expert, the statistical and methodological editors, and at least one consumer. Necessary revisions must be made by the authors and accepted by the editorial team before publication in *The Cochrane Library*.

### Support offered by the Cochrane Skin Group editorial base

The CSG aims to provide worldwide support at the end of an email. When emails get too complicated we are happy to speak by tele-

phone. We will help you create a team. For example, if you as the lead author cannot find team members with the skills you need, our editorial assistant will do all she can by writing to the membership seeking additional co-authors for you.

Upon officially becoming an author, we disseminate a range of documents on a variety of review processes, we highlight available review courses, give tips on avoiding plagiarism, share useful web links (including access to Cochrane's unique online training resources), and provide a guide to the review software. We also offer help with the translation of papers.

If a team is really struggling to complete its review, we will in some cases pay for a freelance systematic reviewer to work with it to offer expert guidance.

## Responsibilities of Cochrane Skin Group author teams

The editorial base expects that a title will be developed into a protocol within 6 months of its registration, and a review will be submitted for consideration for peer review within 15 months of the protocol being published in *The Cochrane Library*. During the title registration process, we ask new teams to sign an Author Agreement confirming their acceptance of these terms.

We ask authors to submit their protocols or reviews in as good a condition as possible to the editorial base. To help achieve this standard, the managing editor will work through the submission and ask you to amend any omissions or errors before it goes to the coordinating editor. Authors can expect the CSG to process protocols from their acceptance at the editorial base to submission to *The Cochrane Library* within 3 months; for reviews this period is 6 months. But the time taken is greatly influenced by how rapidly all the referees reply and how long the authors take to respond to the referees' comments.

To adhere to these timelines, authors are expected to respond to the referees' comments no longer than 1 month or 2 months, for protocols and reviews respectively, after they originally received them. The CSG reserves the right to de-register titles if deadlines are not met. However, we aim to help rather than penalize author teams, and we do all we can to assist and only reluctantly withdraw publications and readvertise for new teams.

## How do review teams find trials?

Review teams work closely with our trials search coordinator (TSC) to identify RCTs for inclusion in their reviews. When a team is working on a protocol, the TSC will work with them to develop a draft search strategy for their topic for MEDLINE, and will advise on which databases and other sources it would be appropriate to search. The TSC uses the draft search strategy as a basis for developing strategies for other databases once the protocol is published and the team is working on the review proper.

The CSG currently advises that in collaboration with the group's TSC, review authors search the following databases as a minimum:

- the Cochrane Skin Group Specialized Register (see below);
- Cochrane Central Register of Controlled Trials (CENTRAL) in *The Cochrane Library*;
- MEDLINE or PubMed;
- EMBASE (a biomedical database that has a particularly comprehensive coverage of pharmacology, drug research and toxicology);
- LILACS (Latin American and Caribbean Health Science Information database).

In addition, we encourage review teams to search the following trials registers to identify trials that may not yet have published reports:

- the metaRegister of Controlled Trials ([www.controlled-trials.com](http://www.controlled-trials.com));
- the US National Institutes of Health Ongoing Trials Register ([www.clinicaltrials.gov](http://www.clinicaltrials.gov));
- the Australian New Zealand Clinical Trials Registry ([www.anzctr.org.au](http://www.anzctr.org.au));
- the World Health Organization International Clinical Trials Registry platform ([www.who.int/trialsearch](http://www.who.int/trialsearch));
- the EU Clinical Trials Register ([www.clinicaltrialsregister.eu/](http://www.clinicaltrialsregister.eu/)).

Teams may also want to search other web-based sources or databases, particularly subject-specific or non-English language resources. They may also wish to hand-search journals or conference proceedings (hand-searching refers to the process of manually checking a physical copy of a journal or conference proceedings by eye) or explore the "grey literature" in order to find additional reports of trials relevant to their review topic. More information on the CSG's searching methods is available [6].

## The Cochrane Skin Group Specialized Register

One of the key resources available to review teams searching for trials is the CSG's Specialized Register, a register of over 9000 (June 2012) reports of controlled trials in dermatology. It contains reports of both RCTs and controlled clinical trials (CCTs) identified by a combination of hand-searching and database searching by the CSG, and is a valuable resource for those preparing systematic reviews on dermatology topics. The Specialized Register is also used to feed new trials into the Central Register of Controlled Trials, part of *The Cochrane Library*.

## The Cochrane Library

The electronic *Cochrane Library* is the main product of the Cochrane Collaboration, and is the place where you will find all our published protocols and reviews.

*The Cochrane Library* (<http://www.thecochranelibrary.com/>) is a collection of seven databases and is the single best source of reliable evidence about the effects of health-care interventions. The databases are as follows:

- The Cochrane Database of Systematic Reviews (CDSR), which contains protocols and reviews prepared and maintained by Cochrane review groups.
- CENTRAL, which contains bibliographic information on controlled trials, including reports from conference proceedings and many other sources not listed in other bibliographic databases.
- The Cochrane Methodology Register (CMR), a bibliography of publications that report on methods used in the conduct of controlled trials.
- The Database of Abstracts of Reviews of Effectiveness (DARE), produced by the Centre for Reviews and Dissemination in England, which contains critical assessments and structured abstracts of other high-quality systematic reviews.
- The Health Technology Assessment (HTA) Database, which brings together details of completed and ongoing health technology assessments (studies of the medical, social, ethical, and economic implications of health-care interventions) from around the world. The HTA database is produced by the Centre for Reviews and Dissemination in England.

- The NHS Economic Evaluation Database, a register of economic evaluations of health-care interventions.
  - About The Cochrane Collaboration database. This database contains information on the 80 groups (Issue 6, 2012) that make up The Cochrane Collaboration.
- CDSR, CENTRAL and About are published monthly. DARE, CMR, HTA and EED are published quarterly.

## The role of consumers

“Consumers,” rather than “patients,” is the term given to people who have the skin disease that is the subject of the review or care for someone with that condition. Participation of consumers in reviews as co-authors, in some cases lead authors, and as referees has always been very important to the CSG. Consumers can help a team clearly describe the social impact of the condition, and define the ultimate aim or question that they are trying to answer in their review; they help to ensure the review is understood by the intelligent layman, and in particular they contribute to the 400-word précis of the review that is the plain language summary.

Where possible, we encourage two or more consumers to work together to produce a combined set of comments on a protocol or review. This is especially valuable when it reflects different geo-economic perspectives.

Following on from their importance to Cochrane and the Cochrane Consumer Network, within the wider department of the Centre of Evidence Based Dermatology in Nottingham, of which the CSG is a part, consumers have contributed notably through the Patient Panel in the development and design of RCTs by the UK Dermatology Clinical Trials Network.

## Impact of our reviews

Cochrane reviews have an impact on the wider community through the reviews themselves and their reputation for quality; through serving to teach about the principles of evidence-based medicine; through products of the review being presented in different ways for different audiences; through different media; through the results being used by various public bodies; and through authors using their Cochrane reviews to apply for grants for research proposals. The Impact Factor is a tool for ranking, evaluating, and comparing journals and is a measure of the frequency with which the “average article” in a journal has been cited in a particular year. The CDSR is ranked in the top 10 out of the 153 journals in the “Medicine, General & Internal” category: the 2011 Impact Factor was 5.9. The impact for CSG reviews in 2010 and 2011 was comparable to the highest rated dermatology journal: the *Journal of Investigative Dermatology*.

## Communicating with different audiences

The plain language summaries, podcasts, and videos aim to reach a wide audience with a succinct message about the core findings of the review.

The structured abstract and the authors’ conclusions highlighting their implications for research and for practice reach those who wish to understand a little more of the subject of the review, and the Cochrane Journal Club aims to promote discussion of reviews within a clinical department.

The full reviews, some of which can be huge documents, are generally only read in their entirety by those with a particular interest in that subject, by professional guideline writers or by those

involved with developing health policies. They can inform and improve health-care decision-making by advising on the design of future clinical trials; for example, in vitiligo [7,8] and in the management of atopic eczema [9,10]; see also the CREAM study at <http://www.controlled-trials.com/ISRCTN96705420/> (N. Francis, unpublished results, 2014).

They can inform guidelines used for setting health policies; for example, minocycline for acne [11,12], topical treatments for chronic plaque psoriasis [13,14], and safety of topical corticosteroids in pregnancy [15,16]. Reviews may also lead to derivative articles [17].

In terms of research commissioning and priority setting, our review on “Interventions for preventing occupational irritant hand dermatitis” [18] has also led to an HTA call for a clinical trial in health-care workers to address uncertainties ([http://www.hta.ac.uk/funding/Outcomestableweb\\_Apr12.pdf](http://www.hta.ac.uk/funding/Outcomestableweb_Apr12.pdf)).

Following The Cochrane Collaboration’s acceptance as a non-governmental organization in official relations with the World Health Organization, the Department of HIV/AIDS at the World Health Organization asked the CSG to assist with guidelines they are writing for treating the skin conditions developed by people with HIV. The CSG supported this work by reviewing the department’s search strategy for finding evidence-based material to support the guidelines.

## Co-publication

The CSG is keen to encourage authors to consider the life their Cochrane reviews will have after publication. We ask authors at the title registration stage to consider publication of summary articles of their reviews to widen dissemination of their findings. The Cochrane review should be published either before or at the same time as the publication in another journal. The CSG has co-publication agreements with the *Journal of the American Academy of Dermatology* and with the *British Journal of Dermatology* [19]. *Clinical & Experimental Dermatology* also publishes summaries of Cochrane reviews.

## Cochrane Skin Group satellites

The Cochrane Collaboration is keen to promote satellite groups around the world who are affiliated to the main editorial bases, to promote evidence-based medicine, Cochrane methods, and to support authors in their countries. We at the UK editorial base are delighted that a French satellite of the CSG was launched in 2012. It will support Cochrane authors in France and in francophone countries, such as Vietnam and Algeria. One of our editors in the USA is currently applying for funding to set up a US satellite of the CSG. In 2010 at the annual CSG meeting, a “comparative effectiveness research” meeting was held in Denver, USA, to promote the concept of evidence-based medicine to American dermatologists. All reviews produced by satellite groups will be submitted to the parent editorial base in Nottingham, UK, and handled like any other Cochrane review.

## Contacting the Cochrane Skin Group editorial base

If you wish to get involved with the CSG, you can do so by doing one or more of the following:

- commenting on published reviews via the feedback facility on *The Cochrane Library*;
- becoming a peer referee for us;
- becoming a review author on a Skin review.

If you are interested, the first thing to do is to contact us at the CSG:

Address: Cochrane Skin Group, The Centre of Evidence-Based Dermatology, Room A103, King's Meadow Campus, University of Nottingham, NG7 2NR

## CHAPTER 5

# Formulating well-built clinical questions

Michael Bigby<sup>1</sup> and Berthold Rzany<sup>2</sup>

<sup>1</sup>Department of Dermatology, Harvard Medical School and Beth Israel Deaconess Medical Center, Boston, MA, USA

<sup>2</sup>RZANY & HUND, Privatpraxis für Dermatologie und Ästhetische Medizin, Berlin, Germany

### Introduction

Practicing evidence-based medicine (EBM) centers on trying to find answers to clinically relevant questions that arise in caring for individual patients. Asking well-built clinical questions may be the most important step in practicing EBM. To benefit patients and clinicians, the questions need to be directly relevant to the patient's problems and phrased in ways that directs the clinician's search to relevant and precise answers [1].

### Tips for building well-built clinical questions

A well-built clinical question has four elements:

- a patient or problem;
- an intervention;
- a comparison intervention (if necessary); and
- an outcome [1–4].

The first component of a well-built clinical question is an accurate description of the patient and problem. Try to generalize the description balancing precision and brevity [1]. The next two components are accurate descriptions of the relevant intervention or interventions. Interventions can be etiologic factors, diagnostic tests, treatments, prognostic factors, or harmful exposures. Several interventions (e.g., many treatments for psoriasis) might be appropriate for inclusion in the question. When the focus is on treatment, the comparative intervention may be an established treatment, another treatment, or a placebo. The final component of the well-built clinical question is a clinically relevant outcome measure that is important to the patient and treating dermatologist.

One easy way of remembering these key components is the acronym PICO: patient, intervention, comparator, and outcome. Well-built clinical questions about individual patients are not only about treatment; they can be grouped into several categories: etiology, diagnosis, therapy, prevention, prognosis, and harm. For example, a 71-year-old man presents with a painful cluster of vesicles on an erythematous base on his left cheek. You suspect he has herpes zoster, although herpes simplex is in your differential diag-

nosis. Examples of well-built clinical questions about diagnosis, therapy, and prognosis would be:

- 1 In an elderly man presenting with a vesicular eruption, is a viral culture or direct fluorescence antibody test more useful in establishing a diagnosis of herpes zoster?
- 2 In an elderly man with acutely painful herpes zoster, would treatment with antivirals, or antivirals and corticosteroids, lead to more rapid resolution of pain and more rapid return to a normal quality of life?
- 3 If an elderly man who presents with acutely painful herpes zoster is treated with antivirals and corticosteroids or is left untreated, how likely is he to develop post-herpetic neuralgia?

In contrast, examples of poorly structured questions about this same patient would be:

- 4 How do you make a diagnosis of herpes zoster?
- 5 What is the best treatment for herpes zoster?
- 6 What is the prognosis of herpes zoster?

In most clinical situations, several well-built clinical questions are possible using the PICO structure (Table 5.1). It is up to the physician and the patient to determine what are the most important questions.

### The advantages of well-built clinical questions

A major benefit of careful and thoughtful question forming is that it makes the search for evidence and the critical appraisal of the evidence found easier. The well-formed question makes it relatively straightforward to elicit and combine the appropriate terms needed to represent your need for information in the query language of whichever database or search service you choose (e.g., Medline, Embase, or the Cochrane Library). Formulating well-built clinical questions will also train you to clearly define your patient or problem, be specific about the interventions used, and choose carefully described and precise desired outcomes. Questions like those in 4, 5, and 6 above will certainly lead to answers. However,

**Table 5.1** The four elements of a well-built clinical question using the PICO (patient, intervention, comparator, and outcome) structure.

	Patient or problem	Intervention	Comparison intervention (if necessary)	Clinically relevant outcome(s)
Tips for building [1]	Starting with your patient, ask "How would I describe a group of patients similar to mine?" Balance precision with brevity.	Ask "Which main intervention am I considering?"	Ask "What is the main alternative to compare with the intervention?"	Ask "What do I want to accomplish?" or "What could this exposure really affect?"
Example 1: diagnosis	In a patient presenting with a vesicular eruption,	... is a viral culture ...	... or a direct fluorescence antibody (DFA) test ...	... more useful in establishing a diagnosis of herpes zoster?
Example 2 treatment		... would treatment with antivirals ...	... or antivirals and corticosteroids ...	... lead to more rapid resolution of pain and more rapid return to a normal quality of life?
Example 3 prognosis	If an elderly patient with acutely painful herpes zoster ...	... is treated with corticosteroids ...	... or is left untreated, ...	... how likely is s/he to develop post-herpetic neuralgia?

obtaining the answer would require a considerable amount of time searching and validating a vast amount of literature. Structuring the question as in those in 1, 2, and 3 above would lead to more specific answers in considerably less time.

**What factors are important in generating well-built questions in a dermatology consultation?**

A well-built and relevant question can only be generated if there has been an accurate initial evaluation of the patient, which includes a detailed history and examination to establish an accurate diagnosis. The patient's characteristics, such as age, gender, past therapy, general health, or allergies, are important. Understanding which factors are important to the patient (e.g., efficacy of treatment, difficulty of treatment regimen, potential side effects, effect on quality of life, or affordability) is also crucial.

Specifying an outcome that is meaningful to the patient is also important. For example, consider a 28-year-old man with psoriasis who is desperate for a remission of the visible plaques on his body, as he was planning to go for a once-in-a-lifetime holiday to the

coast, where he wanted to expose his skin at the beach. Finding trials that only mention a 50% reduction in the psoriasis area and severity index (PASI) scores as their sole outcome measure would be of little value. What would be of most interest to this man are those trials that specify the percentage of patients achieving complete or nearly complete clearing; for example, a 90% reduction of the PASI after a course of therapy.

Asking a clinically relevant well-built question is not as easy as it might appear. It takes practice and is a learnable skill. Ultimately it saves time, and it is more likely to provide useful answers in caring for individual patients.

## CHAPTER 6

# Finding the best evidence

Michael Bigby<sup>1</sup> and Rosamaria Corona<sup>2</sup>

<sup>1</sup>Department of Dermatology, Harvard Medical School and Beth Israel Deaconess Medical Center, Boston, MA, USA

<sup>2</sup>Wolters Kluwer Health, Waltham, MA, USA

The ability to find the best evidence to answer clinical questions is crucial for practicing evidence-based medicine. Finding evidence requires access to electronic searching, searching skills, and available resources. Methods for finding systematic reviews and evidence about etiology (harm), diagnosis, therapy, prognosis, and clinical prediction guides have been well developed [1,2].

Evidence about therapy is the easiest to find. The best sources for finding the best evidence about treatment include:

- 1 The Cochrane Library;
- 2 searching the Medline and Embase databases;
- 3 primary journals;
- 4 secondary journals;
- 5 evidence-based dermatology and evidence-based medicine books (e.g., clinical evidence);
- 6 the National Guideline Clearinghouse (<http://www.jcaai.org>);
- 7 the National Institute for Health and Clinical Excellence (NICE, [www.nice.org.uk](http://www.nice.org.uk)).

The Cochrane Library contains the Cochrane Database of Systematic Reviews of the Treatment Diseases, the Database of Abstracts of Reviews of Effectiveness (DARE), the Cochrane Central Register of Controlled Trials (Central), and the Health Technology Assessment (HTA) database. Volunteers, according to strict guidelines developed by The Cochrane Collaboration, write the systematic reviews in the Cochrane Library. Issue 3 of the 2014 Cochrane Library (accessed 13 March 2014) contained 8367 completed systematic reviews. The number of reviews of dermatological topics is steadily increasing.

Central is a database of over 763 865 controlled clinical trials. It is compiled by searching the Medline and Embase databases, and hand searching many journals. Hand searching journals to identify controlled clinical trials and randomized-controlled clinical trials was undertaken because members of The Cochrane Collaboration noticed that many trials were incorrectly classified in the Medline database. As an example, Dr Finola Delamere of the Cochrane Skin Group, hand searched the *Archives of Dermatology* from 1990 through 1998 and identified 99 controlled clinical trials. Nineteen of the trials were not classified as controlled clinical trials in Medline and 11 trials that were not controlled clinical trials were misclassified as control clinical trials in Medline [3].

DARE is a database of abstracts of systematic reviews published in the medical literature. It contained abstracts and bibliographic details on 28 388 published systematic reviews. DARE is the only database to contain abstracts of systematic reviews that have been quality assessed. Each abstract includes a summary of the review together with a critical commentary about the overall quality.

The HTA database consists of completed and ongoing health technology assessments (studies of the medical, social, ethical, and economic implications of health-care interventions) from around the world. It contained 13 138 assessments in issue 2 of the 2013 Cochrane Library. The aim of the database is to improve the quality and cost effectiveness of health care.

The Cochrane Library is the best source for evidence about treatment. It can be easily searched using simple Boolean combinations of search terms and by more sophisticated search strategies. The Cochrane Database of Systematic Reviews, DARE, Central, and HTA can be searched simultaneously. The Cochrane Library is available on a personal or institutional subscription basis on DVD, and on the World Wide Web from Wiley InterScience (<http://www.thecochranelibrary.com/view/0/HowtoOrder.html>). The Cochrane Library is updated quarterly. The Cochrane Library is offered free of charge in many countries by national provision and by many medical schools in the USA. It should be available at your medical library.

The second best method for finding evidence about treatment and the best source for finding most other types of best evidence in dermatology is by searching the Medline database by computer [2,4]. Medline is the National Library of Medicine's (NLM's) bibliographic database covering the fields of medicine, nursing, dentistry, veterinary medicine, the health-care system, and the pre-clinical sciences. The Medline file contains bibliographic citations and author abstracts from approximately 5600 current biomedical journals published in the USA and 80 other countries. The file contains approximately 19 million records dating back to 1946 [5].

Medline searches have inherent limitations that make their reliability less than ideal [2]. For example, Spuls *et al.* conducted a systematic review of systemic treatments of psoriasis [6]. Treatments analyzed included UVB, PUVA, methotrexate, cyclosporin A, and retinoids. The authors used an exhaustive strategy to find relevant

references, including Medline searches, contacting pharmaceutical companies, polling leading authorities, reviewing abstract books of symposia and congresses, and reviewing textbooks, reviews, editorials, guideline articles, and the reference lists of all papers identified. Of 665 studies found, 356 (54%) were identified by Medline search (range 30–70% for different treatment modalities). The 17 of 23 authorities who responded provided no references beyond those identified by Medline searching.

The key to Medline searching is to find relevant articles and to exclude irrelevant citations. Several useful techniques can greatly aid your ability to accomplish this goal. Searches generally are done on the basis of Boolean combinations of search terms. For example, a search for best evidence about drug treatment of onychomycosis might read [onychomycosis and (terbinafine or itraconazole or fluconazole) not case reports].\* This search would identify articles on onychomycosis using any of the listed drugs and excluding case reports [1,2].

It is important to understand the difference between text word and Medical Subject Headings (MeSH) searching and to be able to do both. Many of the programs used to search the Medline database automatically do text word and MeSH searches. MeSH terms includes all of the terms in the Medical Subject Headings, a controlled vocabulary of keywords used to index Medline. Each Medline citation is given a group of MeSH terms that relate to the subject of the paper from which it is drawn. Frequently, MeSH terms will have an additional subheading, which further defines how the MeSH term relates to the article with which it is associated. This subheading is appended to the MeSH term; for example, “onychomycosis diagnosis.”

Indexing articles is not an exact science. The MeSH headings assigned by the NLM may not coincide with the intent of the author or the majority of searchers for several reasons. Authors may not clearly express their intent, indexers are usually not experts in the field of the article they are indexing, and the mistakes associated with doing repetitive tasks occur [2]. Relevant articles may be missed when they are not assigned the appropriate MeSH heading. Irrelevant articles may be included in a MeSH search if they are assigned to the wrong MeSH heading. For example, The Cochrane Collaboration identified major problems in the Medline indexing of randomized controlled trials [2].

Text word searches allow one to search articles for words within the title and abstract that are important to and coincide with the intent of the author. However, text word searches are subject to several problems. Authors may not describe their methods or objectives well or may make errors in spelling, omission, or commission [2]. The problem of misspelling can be illustrated by doing a text word search for “pruritis” (pruritus spelled incorrectly). This search will yield 114 references in which the word has been misspelled. Many of these references may not be detected in a search for pruritus (spelled correctly) [2].

Boolean topic searches will often contain too many references or too few. They may contain many irrelevant citations and miss many relevant citations. Several techniques will help make searches more sensitive (i.e., pick up relevant citations) and more specific (i.e., exclude irrelevant citations) [2]. To increase the sensitivity of searches, searching both text word and MeSH headings, exploding MeSH headings and using truncation may be helpful. MeSH term searches can be “exploded” to include all terms that are logical

subsets of the term entered [2]. For example, exploding the MeSH term “onychomycosis” will retrieve all of the articles that use that MeSH term, whether they have subheadings or not. Many of the programs used to search the Medline database automatically explode searches of MeSH terms or MeSH Major Topics.

Truncation refers to searching using the root of a word to allow variants of the word to be detected. For example, a search of onychomycosis and controlled clinical trial will detect fewer studies than a search for onychomycosis and control\* (where control\* contains a wild card that will allow detection of all words that begin with the root “control”). Truncation can be performed on text word and MeSH heading searches.

To increase the specificity of searches, selecting specific subheadings of MeSH terms and limiting the search may be helpful. MeSH terms can be limited to specific subheadings to help narrow search results to relevant articles. For example, onychomycosis has subheadings that restrict retrieved articles to ones dealing with diagnosis or drug treatment [2]. Searches can be limited in many ways, including publication type, language, human subjects, and date of publication. Restricting the publication type to randomized controlled trial or case-control study is useful to limit retrieved articles to those of highest quality.

Performing a sensitive or specific search from scratch is often a time-consuming task. Arriving at an efficient search strategy to suit one’s particular needs is sometimes a work of art. Once accomplished, it is important to be able to edit, save, and retrieve the search strategy. The saved strategy can then be used in future searches of different subjects without having to rethink or retype the whole search procedure. The methods for performing these techniques (text word and MeSH searching, exploding, truncation, using subheadings, limiting, and saving) vary by platform used. Mastering them will greatly improve searching efficiency.

Specific search strategies, “filters,” have been developed to help find relevant references and exclude irrelevant references for best evidence about etiology, diagnosis, therapy, prognosis, and clinical prediction guides, and for finding systematic reviews ([http://www.ncbi.nlm.nih.gov/books/NBK3827/#pubmedhelp.Clinical\\_Queries\\_Filters](http://www.ncbi.nlm.nih.gov/books/NBK3827/#pubmedhelp.Clinical_Queries_Filters)) [7,8]. Each type of search can be made narrow (specific) or broad (sensitive). These filters have been incorporated into the PubMed Clinical Queries search engine of the NLM and are available at <http://www.ncbi.nlm.nih.gov/pubmed/clinical> [5]. *PubMed Clinical Queries is the preferred method for searching the Medline database for best, clinically relevant evidence.* It can be freely used by anyone with Internet access.

Clinicians are increasingly using general search engines such as Google, Bing, or Google Scholar to search the Internet for medical information [9]. These search engines are not specifically designed to find the types of evidence needed for clinical decision making. They are much less sensitive and specific in finding clinically useful evidence when compared with PubMed searches with Clinical Queries filters [10].

Embase is Excerpta Medica’s database covering drugs, pharmacology, and biomedical specialties [11]. Embase has better coverage of European and non-English language sources and may be more up to date [11]. The overlap in journals covered by Medline and Embase is about 34% (range 10–75% depending on the subject) [2]. Embase contains over 27 million records from 1947 to the present. Embase is available online (<http://www.embase.com/>).

\* The convention used throughout for search entries is that Boolean operations within parentheses are done first.

Personal and institutional subscriptions are available. Embase.com performs simultaneous searches of Embase and Medline databases and eliminates duplicate records. The filters that are incorporated into the PubMed Clinical Queries search engine can be used to perform clinically relevant searches of Embase with some modification [2,7,8].

Structured abstracts of articles are published in secondary journals (e.g. the Evidence-based Dermatology section of *JAMA Dermatology* and the *British Journal of Dermatology*). The articles are strictly selected on the basis of methodological quality and are accompanied by commentary putting the information in clinical perspective.

Full text versions of many primary journals are now available on the Internet. Access is made available in many hospitals and medical school libraries. Available commercial vendors include Science Direct (<http://www.sciencedirect.com/>), Highwire (<http://highwire.stanford.edu/>), and EBSCO Publishing (<http://www.ebscohost.com/academic/medline-with-full-text>), among others.

The National Guideline Clearinghouse maintains a database of guidelines for the treatment of disease written by panels of experts following strict guidelines of evidence. The database is accessible through the Internet (<http://guideline.gov/>). There are currently more than 100 dermatological topics; however, many have not been recently updated.

NICE (<http://www.nice.org.uk/>) produces guidance on public health, health technologies, and clinical practice based on the best available evidence. Its coverage of dermatological topics is limited,

but it includes guidance for treating atopic eczema, a final appraisal determination on the use of calcineurin inhibitor for atopic dermatitis, the use of biologics for psoriasis, and a full set of guidelines for skin cancer, including melanoma.

## CHAPTER 7

# The hierarchy of evidence

Michael Bigby

Department of Dermatology, Harvard Medical School and Beth Israel Deaconess Medical Center, Boston, MA, USA

Once appropriate questions have been formulated, what is the best evidence to answer these questions? Potential evidence includes personal experience, colleagues or experts, textbooks, and articles published in journals. An important principle of evidence-based medicine (EBM) is the concept of a *hierarchy of evidence* (i.e., that there is a hierarchy in the quality [strength] of evidence) (Figure 7.1) [1,2]. Systematic reviews are scientific summaries of the quality, direction, magnitude, and precision of the evidence. The ordering of the hierarchy of evidence has been widely discussed, actively debated, changed, and sometimes hotly contested [3–7].

Well-conducted systematic reviews of well-performed clinical studies (especially if the studies have results of similar magnitude and direction, and if they are comparable) are most likely to have results that are true and useful. A systematic review is an overview that answers a specific clinical question, contains a thorough, unbiased search of the relevant literature, explicit criteria for assessing studies, and a structured presentation of the results. A systematic review that uses quantitative methods to summarize results is a meta-analysis [3,8].

Meta-analysis allows one to recognize important treatment effects by combining the results of small trials that individually lack the power to demonstrate differences among treatments. For example, the benefits of intravenous streptokinase in acute myocardial infarction were recognized by the results of a cumulative meta-analysis of smaller trials at least a decade before experts recommended it and before large clinical trials showed it to be efficacious [3,4].

Meta-analysis has been criticized for the discrepancies between the results of meta-analysis and the results of large clinical trials [3,5–7]. For example, the results of a meta-analysis of 14 small studies of calcium to treat preeclampsia showed that treatment was effective, whereas a large trial failed to show a treatment effect [3]. The frequency of discrepancies ranges from 10% to 23% [3]. Discrepancies can often be explained by differences in treatment protocols, heterogeneity of study populations, or changes that occur with time [3].

Not all systematic reviews and meta-analyses are equal. Systematic reviews performed in The Cochrane Collaboration are rated among the best, but even then up to a third may contain significant prob-

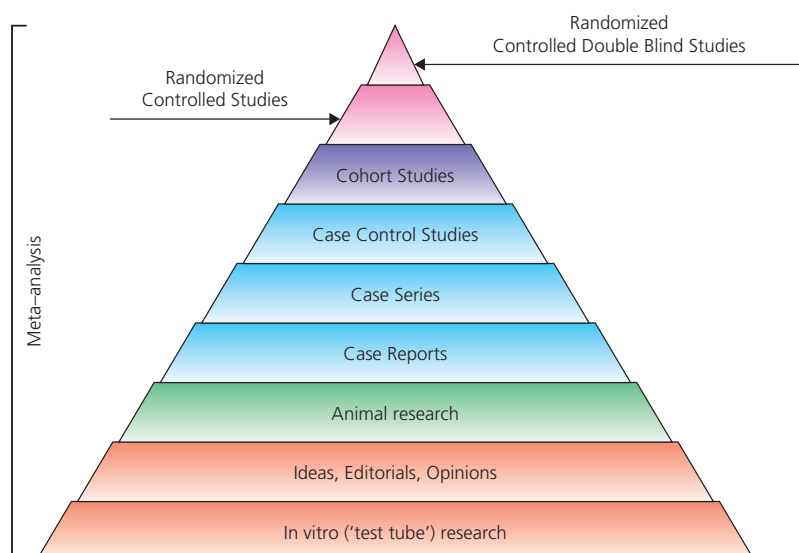

lems [9,10]. Methods exist for assessing the quality of systematic reviews (see Chapter 8) [2,11].

The type of clinical study that constitutes best evidence is determined by what type of question is being asked (Table 7.1) [12]. Questions about diagnosis are best addressed by cohort studies, which include comparisons with a reference standard evaluated in an appropriate spectrum of patients in whom the test is likely to be used [2,11,13,14]. Questions about therapy and prevention are best addressed by randomized controlled trials (RCTs) [2,11,15,16]. Cohort studies or case-control studies best address questions about prognosis, harm, and disease etiology [2,11,17,18]. Methods exist for assessing the quality of each type of evidence (see Chapters 9–14) [2,11].

The randomized controlled clinical trial became the gold standard for determining treatment efficacy in 1948, with the publication of the trial that demonstrated that streptomycin was effective in the treatment of pulmonary tuberculosis [19]. Over 763 865 RCTs are recorded in the Cochrane Controlled Trials Registry, and thousands more exist in an unpublished form [20]. Large, inclusive trials that have concealed randomization, are fully blinded, have clinically relevant outcomes, intention-to-treat analysis, and equal treatment of randomized groups are likely to provide the best possible evidence about effectiveness [21–23]. Studies have demonstrated that failure to use randomization or adequate concealment of allocation resulted in larger estimates of treatment effects, often because of a poorer prognosis in nonrandomly selected control groups in comparison with randomly selected control groups [23].

Expert opinion can be valuable, particularly for rare conditions in which the expert has the most experience or when other forms of evidence are not available. However, several studies have found that expert opinion often lags significantly behind conclusive evidence [1]. Experts should be aware of the quality of existing evidence.

Whereas personal experience is an invaluable part of becoming a competent physician, the pitfalls of relying too heavily on personal experience are widely documented [1,24,25]. Nisbett and Ross extensively reviewed people's ability to draw inferences from personal experience and documented several pitfalls [26]. They include:

**Figure 7.1** The evidence pyramid. Reproduced from SUNY Downstate Medical Center, Medical Research Library of Brooklyn Guide to Research Methods. The Evidence Pyramid. SUNY Health Sciences, Evidence Based Medicine Course <http://library.downstate.edu/EBM2/2100.htm>.

**Table 7.1** Strength of recommendation taxonomy (SORT) based on levels of evidence.

Strength of recommendation	Level of evidence needed	Definitions		
		Treatment/prevention	Diagnosis	Prognosis
A Recommendation based on consistent and good-quality patient-oriented evidence. <sup>a</sup>	1. Consistent and good patient-oriented evidence.	Systematic review (SR)/ meta-analysis of RCTs with consistent findings. High-quality individual RCT. <sup>b</sup> All-or-none study. <sup>c</sup>	Validated clinical decision rule. SR/meta-analysis of high-quality studies. High-quality diagnostic cohort study. <sup>d</sup>	SR/meta-analysis of good-quality cohort studies. Prospective cohort study with good follow-up.
B Recommendation based on inconsistent or limited-quality patient-oriented evidence. <sup>a</sup>	2. Inconsistent or limited-quality patient-oriented evidence.	SR/meta-analysis of lower-quality clinical trials or of studies with inconsistent findings. Lower-quality clinical trial. <sup>b</sup> Cohort study. Case-control study.	Unvalidated clinical decision rule. SR/meta-analysis of lower-quality studies or studies with inconsistent findings. Lower-quality diagnostic cohort study or diagnostic case-control study. <sup>c</sup>	SR/meta-analysis of lower-quality cohort studies or with inconsistent results. Retrospective cohort study or prospective cohort study with poor follow-up. Case-control study. Case series.
C Recommendation based on other evidence.	3. Other evidence.	Consensus, usual practice, opinion, disease-oriented evidence (intermediate or physiologic outcomes only), or case series for studies of diagnosis, treatment, prevention, or screening.		

Reproduced from Ebell *et al.* [12], with permission from American Academy of Family Physicians.

<sup>a</sup>Patient-oriented evidence measures outcomes that matter to patients: morbidity, mortality, symptom improvement, cost reduction, and quality of life. Disease-oriented evidence measures intermediate, physiologic, or surrogate end points that may or may not reflect improvements in patient outcomes (e.g., blood pressure, blood chemistry, physiologic function, pathologic findings).

<sup>b</sup>High-quality RCT: allocation concealed, blinding if possible, intention-to-treat analysis, adequate statistical power, adequate follow-up (greater than 80%).

<sup>c</sup>In an all-or-none study, the treatment causes a dramatic change in outcomes, such as antibiotics for meningitis or surgery for appendicitis, which precludes study in a controlled trial.

<sup>d</sup>High-quality diagnostic cohort study: cohort design, adequate size, adequate spectrum of patients, blinding, and a consistent, well-defined reference standard.

\*By homogeneity, we mean a systematic review that is free of worrisome variations (heterogeneity) in the directions and degrees of results between individual studies.

<sup>†</sup>Met when *all* patients died before the treatment became available, but some now survive on it; or when some patients died before the treatment became available, but *none* now die on it.

- overemphasis of vivid anecdotal occurrences and underemphasis of significant statistically strong evidence;
- bias in recognizing and accepting evidence that supports one's own beliefs, and parallel failure to recognize or accept evidence that contradicts one's own beliefs;
- persistence of beliefs in spite of overwhelming evidence presented against them.

Textbooks appear to be a valuable source of evidence, but they have serious shortcomings. First, by virtue of the way in which they

are written, produced, and distributed, most are about 2 years out of date at the time of publication. Most textbook chapters are narrative reviews that do not consider the quality of the evidence reported [1,2]. They tend to reflect the biases and shortcomings of the experts who write them.

More detailed studies of the relationship of study type and the direction and magnitude of purported benefit are needed in dermatology to guide dermatologists on the relative merits of different study designs. In the meantime, the hierarchy of evidence should

not be conceptualized as a linear phenomenon (i.e., as a scale going from “good” to “bad”). The quality and relevance of evidence should be considered. Thus, a well-conducted large cohort study may be more reliable than a small RCT that has violated most aspects of good RCT design and reporting. Similarly, a small RCT of moderate quality dealing with the exact problem about which the patient is complaining (e.g., palmoplantar psoriasis) is likely to be more useful than a large RCT dealing with a different or broader problem (e.g., psoriasis).

# Appraising systematic reviews and meta-analyses

Michael Bigby<sup>1</sup> and Hywel C. Williams<sup>2</sup>

<sup>1</sup>Department of Dermatology, Harvard Medical School and Beth Israel Deaconess Medical Center, Boston, MA, USA

<sup>2</sup>Centre of Evidence-Based Dermatology, University of Nottingham, Nottingham, UK

## Introduction

A systematic review is an overview that answers a specific clinical question, contains a thorough, unbiased search of the relevant literature, explicit criteria for assessing studies, and structured presentation of the results. Put simply, a systematic review is a review that is done systematically. A systematic review that incorporates quantitative pooling of several similar studies to produce an overall summary of treatment effects is a meta-analysis [1,2]. Meta-analysis provides an objective and quantitative summary of evidence that is amenable to statistical analysis [1]. Meta-analysis allows recognition of important treatment effects by combining the results of small trials that individually might have lacked the power to consistently demonstrate differences among treatments. In conducting a meta-analysis, authors should recognize the importance of having clear objectives, explicit criteria for study selection, an assessment of the quality of included studies, and criteria for which studies can be combined. Meta-analysis is not appropriate if the included studies are very different. Meta-analyses that are not conducted within the context of a systematic review should be viewed with great caution [3].

In summary, a systematic review can be viewed as a scientific and systematic examination of the available evidence. A good systematic review will have explicitly stated objectives (the focused clinical question), materials (the relevant medical literature), and methods (the way in which studies are assessed and summarized). The steps taken during a systematic review are shown in Table 8.1. Just like good randomized controlled trials, protocols describing the plans of a systematic review should be published in the public domain before the review is undertaken, in order to avoid *post hoc* data dredging and biased reporting of results. Such is the practice of The Cochrane Collaboration, where protocols and completed reviews can be compared ([www.thecochranelibrary.com](http://www.thecochranelibrary.com)), along with forced headings in the completed review for the reader to see where the final review has departed from the published protocol along with reasons. Protocols for systematic reviews that are not published in the *Cochrane Library* should be registered with PROSPERO – an international prospective register for systematic reviews based at the Centre of Reviews and Dissemination in York, UK <http://www.crd.york.ac.uk/PROSPERO/>.

Not all systematic reviews and meta-analyses are equal. A systematic review should be conducted in a manner that will include all of the relevant trials (including unpublished trials), minimize the introduction of bias, and synthesize the results to be as truthful as possible and as useful to clinicians as possible. The criteria for critically appraising systematic reviews and meta-analyses are shown in Table 8.2. In general, these criteria are similar to the criteria used to appraise the individual studies that make up the systematic review. Detailed explanations of each criterion are available [1,4]. Other tools, such as AMSTAR (“assessment of multiple systematic reviews”), have been developed to assess the methodological quality of systematic reviews, building upon previous tools, empirical evidence, and expert consensus [5].

The quality of reporting of systematic reviews is highly variable. One cross-sectional study of 300 systematic reviews published in Medline by Moher *et al.* showed that over 90% were reported in specialty journals [6]. Funding sources were not reported in 40% of reviews. Only two-thirds reported the range of years that the literature was searched for trials. Around a third of reviews failed to provide a quality assessment of the included studies, and only half of the reviews included the term “systematic review” or “meta-analysis” in the title. Similar results have been found for dermatological systematic reviews of common skin disorders [54].

Guidelines for better reporting of systematic reviews were established in 1999 by the Quality of Reporting of Meta-Analyses initiative and revised in 2009 [7,8] – preferred reporting items for systematic reviews and meta-analyses (PRISMA). Many journals now insist on reporting systematic reviews in accordance with the PRISMA checklist [8].

## Asking a clear question

Like the well-built clinical question for individual studies, a focused clinical question for a systematic review should contain four elements:

- a patient, group of patients, or problem;
- an intervention;
- comparison interventions;
- specific outcomes [9].

The patient populations should be similar to the majority of patients seen in the population to which one wishes to apply the results of the systematic review. The interventions studied should ideally be those commonly available in practice. Outcomes reported should be those that are most relevant to physicians and patients. Main outcomes should be previously specified in a published protocol, in order to avoid problems with *post hoc* data dredging.

### Sources of evidence within a systematic review

The majority of systematic reviews in dermatology involve therapy, although systematic reviews of diagnostic tests [10], etiology [11], and even mechanisms [12] are emerging. Randomized, controlled clinical trials should be used for systematic reviews of therapy if they are available, because they are generally less susceptible to selection and information bias in comparison with other study designs. The quality of included trials is assessed using the criteria that are used to evaluate individual randomized, controlled clinical trials. The quality criteria commonly used include concealed, random allocation; groups similar in terms of known prognostic factors; equal treatment of groups; blinding of patients, researcher, and analyzers of the data to treatment allocation; and accounting for all patients entered into the trial when analyzing the results (intention-to-treat design). In Cochrane reviews, graphical “risk of bias” displays are provided of how these key elements vary according to included studies [13].

**Table 8.1** The steps involved in undertaking a systematic review.

1 Asking a clear, focused question
2 Formulating the methods by which the evidence will be found, appraised, analyzed, and reported
3 An explicit and thorough search of the literature
4 Data extraction
5 Critical appraisal of the quality of the primary studies and of their results
6 Reporting the results with quantitative pooling of the data, if appropriate
7 Interpretation of the data, including implications for clinical practice and further research

Randomized controlled trials are rarely a reliable source for identifying adverse reactions, unless they are very common. Evidence sources such as case-control studies, case reports, and postmarketing surveillance studies should therefore be examined [14]. Systematic reviews of treatment efficacy should always include a thorough assessment of common and serious adverse events as well as efficacy, in order to come to an informed and balanced decision about the utility of a treatment. A thorough assessment of adverse events should include data from randomized controlled trials, case-control and postmarketing surveillance studies, and some of the other sources shown in Table 8.3.

### The hazards of “quick” searches

A sound systematic review can be performed only if most or all of the available data are examined. An explicit and thorough search of the literature should be performed. It should ideally include searching several electronic bibliographic databases, no language restrictions, scrutiny of citation lists in retrieved articles,

**Table 8.2** Critical appraisal of a systematic review.

#### Are the results of this systematic review valid?

- Did the review address a focused clinical question?\*
- Were the criteria used to select articles for inclusion appropriate?\*
- Is it unlikely that important, relevant studies were missed?†
- Was the validity of the included studies appraised?†
- Were assessments of studies reproducible?†
- Were the results similar from study to study?†

#### Are the valid results of this systematic review important?

- What are the overall results of the review in terms of magnitude of benefit or harm?
- How precise were the results?

#### Can you apply this valid, important evidence in caring for your patient?

- Can the results be applied to my patient's care?
- Were all clinically important outcomes considered?
- Are the benefits worth the harms and costs?

hand-searching for conference reports, prospective trial registers, contacting key researchers, authors, and drug companies.

Simply performing a quick Medline search using “clinical trial” as the publication type is rarely adequate, because complex and sensitive search strategies are needed in order to identify all potential trials, and because some clinical trials will be missed if they are published in a journal not listed by Medline [15]. Potential sources for finding studies about treatment include: the Cochrane Central Register of Controlled Trials (CENTRAL), which is part of the *Cochrane Library*, Medline, Embase, Literatura Latino Americana em Ciências da Saúde (LILACS), bibliographies of studies, review articles and textbooks, symposia proceedings, ongoing trial registries (such as those included in the WHO International Clinical Trials Registry Platform), pharmaceutical companies, and contacting experts in the field.

CENTRAL is a database of over 763 865 controlled clinical trials (March 2014) and is the largest and most complete database of clinical trials worldwide. CENTRAL has been compiled through several complex searches of the Medline and Embase databases, and by hand-searching many journals – a process that is quality controlled and monitored by The Cochrane Collaboration. Hand-searching journals to identify controlled clinical trials and randomized, controlled clinical trials was undertaken because members of The Cochrane Collaboration noticed that many trials were incorrectly classified in the Medline database. As an example, Adetugbo *et al.* hand-searched the journal *Clinical and Experimental Dermatology* for randomized controlled trials from its inception in 1976 through 1997 and identified 73 controlled clinical trials, yet only 31 of these could be identified from a Medline search using “clinical trial” as the publication type [16].

Medline is the National Library of Medicine bibliographic database covering the fields of medicine, nursing, dentistry, veterinary medicine, the health-care system, and the preclinical sciences. The Medline file contains bibliographic citations and author abstracts from approximately 5600 current biomedical journals published in the USA and 80 other countries. The file contains approximately 20 million records, dating back to the mid 1940s (<http://www.nlm.nih.gov/pubs/factsheets/medline.html>).

Embase is Excerpta Medica’s database covering drugs, pharmacology, and biomedical specialties [1]. Embase has better coverage of European and non-English-language sources and may be more up to date [1]. The overlap in journals covered by Medline and Embase is about 34% (range 10–75%, depending on the subject) [13,17]. Embase contains over 25 million records from 7000 journals from 1947 to the present. Embase is available online (<http://www.embase.com>). Personal and institutional subscriptions are available. Embase.com performs simultaneous searches of the Embase and Medline databases and eliminates duplicate records.

LILACS is a database covering more than 600 medical journals from the Latin America and Caribbean region. LILACS can be searched free of charge in Spanish, Portuguese, and English (<http://bases.bireme.br/cgi-bin/wxislind.exe/iah/online/?IsisScript=iah/iah.xis&base=LILACS&lang=i&form=F>). Many of the journals covered are not included in other databases.

## Publication and selective reporting outcome bias

Publication bias (i.e., the tendency that studies that show positive effects are more likely to be published and are easier to find) is an important concern for systematic reviews, and a useful review of

this subject can be found elsewhere [18]. It results from allowing factors other than the quality of the study to influence its acceptability for publication. Several studies have shown that factors such as the sample size, financial conflicts of interest, the direction and statistical significance of findings, or the investigators’ perceptions of whether the findings are “interesting” are related to the likelihood of publication [19,20].

Language bias may also be a problem – that is, the tendency for studies that are “positive” to be published in an English-language journal and also more quickly than inconclusive or negative studies [21]. A thorough systematic review should therefore include a search for high-quality unpublished trials and should not restrict itself to journals published in English.

Studies with small samples are less likely to be published, especially if they have negative (or more often inconclusive) results [19,20]. By emphasizing only those studies that are positive, this type of publication bias jeopardizes one of the main goals of meta-analysis (i.e., an increase in power when pooling the results of small studies). The creation of study registers (e.g., those included in the WHO International Clinical Trials Registry Platform, <http://www.who.int/ictpr/en/>) and advance publication of research designs have been proposed as ways to prevent publication bias [22,23].

Methods for exploring the publication bias include the use of a simple graphic test (funnel plot), by calculating the fail-safe *N*, Begg’s rank correlation method, Egger regression method, and others. [24,25] These techniques are of limited value when less than 10 randomized controlled trials are included. Rigorous testing for publication bias is often not possible in systematic reviews of skin diseases, owing to the limited number and sizes of trials.

For many diseases, the studies published are dominated by drug-company-sponsored trials of new, expensive treatments. Such studies are almost always “positive” [26,27]. Such a bias in publication can result in data-driven systematic reviews that draw more attention to those medicines. In contrast, question-driven systematic reviews answer the clinical questions of most concern to practitioners. In many cases, studies that are of most relevance to doctors and patients have not been done in the field of dermatology, owing to inadequate sources of independent funding. Systematic reviews that have been sponsored directly or indirectly by industry are also prone to bias through overinclusion of unpublished “positive” studies that are kept “on file” by that company [28]. Until it becomes mandatory to register all clinical trials conducted on human beings in a central registry and to make all of the results available in the public domain, distortions may occur due to selective withholding or release of data. Thankfully, some dermatology journals now require all their published trials to have been registered beforehand.

Selective reporting outcome bias – the tendency to highlight only those outcomes out of many that look positive after the analysis has been done – is another serious concern, not only in randomized controlled trials [29], but also in systematic reviews. For example, in the absence of a pre-published systematic review protocol as is required in Cochrane reviews, it is impossible to say whether the outcomes of a published review reflect the important ones that were selected before the review was done, or whether they simply reflect a data-driven process simply because those were the outcomes that looked best [30].

Generally, reviews that have been conducted by volunteers in The Cochrane Collaboration are of better quality than non-Cochrane reviews [31,32]. However, potentially serious errors have been noted in up to a third of such reviews [33].

## Data abstraction

In general, the studies included in systematic reviews are reviewed by at least two reviewers for eligibility, according to prespecified inclusion and exclusion criteria. Data such as the numbers of people entered into studies, numbers lost to follow-up, effect sizes, and quality criteria are recorded on predesigned data abstraction forms by at least two reviewers. Differences among reviewers are usually settled by consensus or by a third arbitrator. A systematic review in which there are large areas of disagreement among reviewers should lead the reader to question the validity of the review.

## Pooling results

Results in the individual clinical trials that make up a systematic review may be similar in magnitude and direction (e.g., they may all indicate that treatment A is superior to treatment B by a similar magnitude). Assuming that publication bias can be excluded, systematic reviews with studies that have results that are similar in magnitude and direction provide results that are most likely to be true and useful. It may be impossible to draw firm conclusions from systematic reviews in which studies have results of widely different magnitude and direction.

The magnitude of the difference between the treatment groups in achieving meaningful outcomes is the most useful summary result of a systematic review. The most easily understood measures of the magnitude of the treatment effect are the difference in response rate and its reciprocal, the number needed to treat (NNT) [1,4]. The NNT represents the number of patients one would need to treat in order to achieve one additional cure. Whereas the interpretation of NNT might be straightforward within one trial, interpretation of NNT requires some caution within a systematic review, as this statistic is highly sensitive to baseline event rates. For example, if a treatment A is 30% more effective than treatment B for clearing psoriasis, and 50% of people on treatment B are cleared with therapy, then 65% will clear with treatment A. These results correspond to a rate difference of 15% (65% – 50%) and an NNT of 7 (1/0.15). This difference sounds quite worthwhile clinically. But if the baseline clearance rate for treatment B in another trial or setting is only 30%, the rate difference will be only 9% and the NNT now becomes 11, and if the baseline clearance rate is 10%, then the NNT for treatment A will be 33, which is perhaps less worthwhile. In other words, it rarely makes sense to provide one NNT summary measure within a systematic review, because “control” or baseline event rates usually differ considerably between studies, due to differences in study populations, interventions, and trial conditions [34]. Instead, a range of NNTs for a range of plausible control event rates that occur in different clinical settings should be given, along with their 95% confidence intervals, as can be found for “summary of findings” tables used in Cochrane systematic reviews produced since 2011 [35]. Further examples of NNTs in dermatology are to be found elsewhere [36].

The precision of the estimate of the differences among treatments should be estimated. The confidence interval provides a useful measure of the precision of the treatment effect [1,4,37,38]. The calculation and interpretation of confidence intervals have been extensively described [38]. In simple terms, the reported result (known as the “point estimate”) provides the best estimate of the treatment effect. The population or “true” response to treatment will most likely lie near the middle of the confidence interval and will rarely be found at or near the ends of the interval. The population or true response to treatment has only a 1 in 20 chance of being outside of the 95% confidence interval.

The point estimates and confidence intervals of the individual trials and the synthesis of all trials are typically displayed graphically in a forest plot (Figure 8.1) [39]. Results are often expressed as the odds ratio of the treatment effect (i.e., the odds of achieving a good outcome in the treated group divided by the odds of achieving a good result in the control group) but can be expressed as risk differences (i.e., difference in response rate) or relative risk (probability of achieving a good outcome in the treated group divided by the probability in the control group). Because odds ratios tend to overestimate the true risk if the outcomes are common, as in many dermatology settings [40], relative risk is most often used in Cochrane Skin Group reviews. A relative risk (or odds ratio) of 1 (null) indicates no difference between treatment and control and is usually represented by a vertical line passing through 1 on the x-axis. A relative risk of greater than or less than 1 implies that the treatment is superior or inferior to the control respectively. The point estimate of individual trials is indicated by a square whose size is proportional to the size of the trial (i.e., number of patients analyzed). The precision of the trial is represented by the 95% confidence interval that appears in forest plots as the brackets surrounding point estimate. If the 95% confidence interval (brackets) does not cross null (relative risk of 1), then the individual trial is statistically significant at the  $P = 0.05$  level [39]. The summary value for all trials is shown graphically as a parallelogram whose size is proportional to the total number of patients analyzed from all trials. The lateral tips of the parallelogram represent the 95% confidence interval, and if they do not cross null (relative risk of 1) then the summary value of the meta-analysis is statistically significant at the  $P = 0.05$  level. Relative risks and odds ratios can be converted to risk differences and NNTs if the event rate in the control group is known (<http://www.cebm.net/index.aspx?o=1044>).

Certain conditions must be met when meta-analysis is performed to synthesize results from different trials. The trials should have conceptual homogeneity. They must involve similar patient populations, have used similar treatments, and have measured results in a similar fashion at a similar point in time. There are two main statistical methods by which results are combined: using random-effects models and fixed-effects models. Random-effects models assume that the different studies’ results may come from different populations with varying responses to treatment. Fixed-effects models assume that each trial represents a random sample of a single population with a single response to treatment. In general, random-effects models are more conservative (i.e., random-effects models are less likely to show statistically significant results than fixed-effects models). When the combined studies have statistical homogeneity (i.e., when the studies are reasonably similar

**Figure 8.1** Typical forest plot showing the results of a meta-analysis of trials of tacrolimus 0.1% ointment versus vehicle in the management of moderate to severe atopic dermatitis. The X-axis represents the rate ratio of the investigator global assessment of response. Reproduced from Ashcroft *et al.* [53], with permission from the BMJ.

in direction, magnitude, and variability), random-effects and fixed-effects models give similar results.

The key principle when considering combining results from several studies together is that conceptual homogeneity precedes statistical homogeneity. In other words, results of several different studies should not be combined if it does not make sense to combine them – for example, if the patient groups or interventions studied are not sufficiently similar to each other. Although what constitutes “sufficiently similar” is a matter of judgment, the important thing is to be explicit about one’s decision to combine or not combine different studies. Tests for statistical heterogeneity are typically of low power, so that statistical homogeneity does not mean clinical homogeneity. Statistical heterogeneity is typically measured in Cochrane reviews using the  $I^2$  statistic [41], with values of greater than 50% representing substantial heterogeneity. When evidence of heterogeneity is found, reasons for heterogeneity between studies – such as different disease subgroups, intervention dosage, or study quality – should be sought [42].

Sometimes, the robustness of an overall meta-analysis is tested further by means of a sensitivity analysis. In a sensitivity analysis, the data are reanalyzed, excluding those studies that are of low quality or because of certain patient factors such as disease subtype, to see whether their exclusion makes a substantial difference in the direction or magnitude of the main original results. In some systematic reviews in which a large number of trials have been performed, it is possible to evaluate whether certain subgroups (e.g., children vs adults) are more likely to benefit than others. Subgroup analysis is rarely possible in dermatology, because few trials are available. Subgroup analyses should always be prespecified in a systematic review protocol in order to avoid spurious post hoc claims. In very large systematic reviews, it is sometimes possible to determine which factors predict the magnitude of treatment success by a form of analysis known as meta-regression [43].

## Interpretation of the data

The conclusions in the discussion section of a systematic review should closely reflect the data that have been presented within that review. The authors should make it clear which of the treatment recommendations are based on the review data and which reflect their own judgments. Cochrane reviews now also include a “summary of findings” table, in addition to the review abstract and lay summary, which summarizes the key information on the quality of evidence, the magnitude and direction of effect of the interventions examined, and the sum of available data on all important outcomes for a given comparison. The quality of evidence in a summary of findings table is usually graded as high, moderate, low, or very low on applying the five criteria (limitations in the design suggesting high likelihood of bias, indirectness of evidence, unexplained heterogeneity or inconsistency of results, imprecision of results and high probability of publication bias) as recommended by the Grading of Recommendations Assessment, Development and Evaluation working group [44].

In addition to making clinical recommendations of therapies when evidence exists, many reviews in dermatology find little evidence to address the questions posed. A lack of conclusive evidence does not mean that the review is a waste of time, especially if the question addressed appears to be an important one [45]. For example, the systematic review of antistreptococcal therapy for guttate psoriasis provided the authors with an opportunity to call for primary research in this area, and to make recommendations

on study design and outcomes that might help future researchers [46]. Some reviewers have gone into more depth in using systematic reviews of many inconclusive quality studies to suggest key aspects of study design relating to patients, intervention, comparator, and outcome that need to be considered in future trials [47].

Applying evidence summarized in a systematic review to specific patients requires the same processes that are used to apply the results of individual controlled clinical trials to patients (see Chapter 18).

## Overviews and network meta-analysis

Overviews of systematic reviews are essentially an overarching review of all systematic reviews in a given topic. Also known as “umbrella reviews,” they emerged from The Cochrane Collaboration as a means of bringing together several separate reviews of different interventions for a particular condition. Such reviews may also include non-Cochrane reviews, and like a normal systematic review, quality assessment of included reviews and pooling of studies is performed, as was done in an overview of systematic reviews of prevention of atopic eczema [48].

*Network meta-analysis* within a systematic review refers to a form of meta-analysis whereby three or more treatments are compared directly using comparisons of interventions within randomized controlled trials and indirectly across trials based on a common comparator. In other words, if treatment A is compared with treatment B, and treatment B is compared with treatment C in a similar population, then it should be possible to make inferences about a comparison of treatment A versus treatment C since they have shared the same comparator. Such techniques are useful in at least three respects. The first is that they may provide essential data to guide health-care professionals or providers on how two new drugs that have only been compared against placebo compare against each other. The second is that they can inform ranking of efficacy of several drugs used for the same condition [49]. Finally, network meta-analysis provides a geometrical picture of which comparisons have been favored and which have been deliberately avoided in order to make certain drugs appear more effective than they really are [50]. Like any other study design, network meta-analysis has to be designed and conducted with rigor [51], and also has to consider the impact of reporting bias on the ranking of the various treatments included [52].

## CHAPTER 9

# How to critically appraise a randomized controlled trial

Hywel C. Williams

Centre of Evidence-Based Dermatology, University of Nottingham, Nottingham, UK

### The place of randomized controlled trials

The rationale and history of the randomized controlled trial is covered extensively in The James Lind Library ([www.JamesLindLibrary.org](http://www.JamesLindLibrary.org)), a nonprofit organization and free online resource that explains the development of fair tests in medicine. Although numerous examples of attempts at fair tests can be found, such as the controlled trial by James Lind in 1762 on the value of lemons in preventing scurvy for British sailors, many recognize the first well-documented randomized controlled trial (RCT) as that performed by the Medical Research Council on the use of streptomycin for the treatment of pulmonary tuberculosis in 1948 [1]. Many variants of clinical trials have developed since then, yet the basic principles of using concealed randomization as the fairest method of allocating study participants to an experimental versus control treatment and the blinded assessment of outcome has remained essentially the same. The RCT remains the most robust study to minimize the effects of bias when trying to assess the degree of effectiveness of a clinical intervention [2]. Yet, as with any study design, there are good and bad RCTs, and this chapter aims to guide the reader on how to tell them apart. As Naldi discusses in Chapter 10, RCTs are not the best source of study design to assess the potential harms of new treatments, especially for less common adverse effects [3].

It should be mentioned at the outset of this chapter that, as highlighted in Chapters 7 and 8, single RCTs should ideally be interpreted within the context of a high-quality systematic review of *all* relevant RCTs. The results of an isolated RCT, even when published in highly prestigious journals, can be hazardous when read in isolation. Thus, Ioannidis showed that of 49 original clinical research studies (almost all were RCTs) published in three major journals and cited over 1000 times, the effectiveness claims of around a third appeared to be exaggerated or contradicted by subsequent research [4]. Large treatment effects reported in initial small studies are especially hazardous, as effect sizes are shown to be smaller when additional trials are performed [5]. Such studies underline the notion that one RCT is seldom enough. The practicing dermatologist should aim to refer to high-quality systematic reviews as their first port of call for comprehensive evidence when available.

### Definitions of quality, validity, and bias

Quality, when referring to RCTs, is a multidimensional concept that includes appropriateness of design, conduct, analysis, reporting, and its perceived clinical relevance [6–9]. Validity refers to the extent to which the study results relate to the “truth.” Validity may be internal (i.e., are the results of *this* trial true?) or external (to what extent do the results of this trial apply to *my* patients?). Factors affecting external validity are discussed further in Chapter 18. It is no good starting to examine factors affecting external validity unless the reader is assured of the internal validity of an RCT – in other words, internal validity is a prerequisite for external validity.

Most readers will be familiar with the need to estimate the role of chance when interpreting results from RCTs. Once the basic lessons in interpreting *P* values and confidence intervals have been achieved, the role of chance as an alternative explanation of study results is usually an easy exercise, especially since such information is usually accessible in almost all published RCTs. In addition to assessing the role of chance, a crucial component in appraising the internal validity of a trial is assessment of its potential for bias. Bias denotes a systematic error resulting in an incorrect estimation of the true effect. Unlike the role of chance, which is usually explicit and well highlighted within RCT reports, the role of bias needs to be specifically searched for and assessed. With respect to clinical trials, bias may be best understood in terms of:

- Selection bias – resulting in an imbalance in treatment groups.
- Performance bias – treating one group of people differently from the other.
- Detection bias – biased assessment of outcome resulting from lack of blinding.
- Attrition bias – biased handling of deviations from the study protocol and those lost to follow-up.
- Selectively reporting outcomes bias – only reporting a selection of the outcomes.
- Publication bias – although *publication bias* (the tendency to conceal or delay publishing “negative” studies – see Chapter 8) is of great significance when it comes to assessing the effects of treatment during the conduct of systematic reviews of RCTs, I also mention it here because of its pernicious effects in distorting the

scientific record and because publication plans should be part of the design and conduct of all individual RCTs.

## How to tell a good dermatological randomized controlled trial from a bad one

### Quality criteria derived from research

Four main factors related to study reporting have been associated with altering the estimation of the risk estimate, usually by inflating the claimed benefit [8]. These are shown in Box 9.1, and are still considered today as the four most important indicators of RCT quality.

### Generation and concealment of treatment allocation

Generation and concealment of treatment allocation are two inter-related steps in the crucial process of randomization. The first refers to the method used to generate the randomization sequence. The second refers to the subsequent steps taken by the trialists to conceal the allocation of participants to the intervention groups from participants and those recruiting trial participants. Both aspects are designed to minimize selection bias, so that participants in a trial are allocated to one treatment or another on the basis of chance only.

Suggestions for adequate and inadequate definitions of the generation of randomization and subsequent concealment are shown in Box 9.2. Additional guidance is available in the *Cochrane Handbook* [10]. Studies that do not describe *how* the randomization sequence was generated should be viewed with some suspicion, given that humans frequently subvert the intended aims of randomization [11].

Concealing the allocation of interventions from those recruiting participants is a crucial step in the progress of an RCT. The randomization list should be kept away from enrollment sites (for

example, by a central clinical trials office or pharmacy). Internet randomization by a third party such as a clinical trials unit [12], whereby details of a new potentially eligible trial participant are entered irrevocably onto a trial database before an allocation code is offered, is another very secure way of concealing allocation. Less ideally, sealed opaque envelopes are used – a method that is still susceptible to tampering by opening the envelopes or holding them up against a bright light [11]. Failure to conceal such allocation means that those recruiting patients can foresee which treatment a patient is about to have. Such lack of concealment can result in selective enrollment of patients on the basis of prognostic factors [13], and loss of the critical “even playing field” that randomization was designed to achieve.

Motives for interfering with the randomization schedule include a desire on the part of investigators to ensure that their new treatment is successful by deliberately allocating patients in a better prognostic group to the new treatment. Another reason may be that a doctor wants to ensure that particular patients for whom they have sympathy are not allocated to a control or placebo group if their belief in the experimental treatment is high. Such selective recruitment is a form of selection bias, resulting in an unfair comparison of the interventions under evaluation. Trials in which concealment of allocation was judged to have been inadequate were found to have inflated the estimates of benefit by about 30% in comparison with studies reporting adequate concealment [8]. Although concealment of allocation may help with subsequent blinding of assessors and patients when recording outcomes, it refers to a process that occurs *before* participants enter the trial, and its prime purpose is to ensure that the groups to be compared are as similar as possible to each other. Whereas blinding of participants and assessors is sometimes not possible – for example, in some surgical procedures in which a sham operation might be considered unethical – concealment of allocation is *always* possible.

**Box 9.1** Factors to consider when assessing the validity of clinical trials in dermatology

#### The “big four” that should always be assessed

- Is the method of generating the randomization sequence and subsequent concealment of allocation of participants clearly described and appropriate?
- Were participants and study assessors blind to the intervention?
- Were all those who originally entered the study accounted for in the results and analysis (i.e., was an intention-to-treat (ITT) analysis performed)?
- Did the authors present the primary outcomes they planned to present or did they highlight only those outcomes that “looked good”?

#### Other factors worth looking for

- Did the study investigators use an adequate disease definition?
- Were the treatment groups similar with respect to predictors of treatment response at baseline?
- Were the outcome measures clinically meaningful to you and your patient?
- Did the investigators do an appropriate statistical test?
- Did the investigators test the right thing (i.e., between-group differences rather than just differences from baseline)?
- Have the authors misinterpreted no evidence of an effect as being evidence of no effect?
- Were the groups treated equally except for the interventions studied?
- Who sponsored the study? Could sponsorship have affected the results or the way they were reported?
- Is the trial clearly and completely reported?

### Blinding (masking) the intervention

Blinding or masking is the extent to which trial participants and others involved in the study assessments are kept unaware of treatment allocation. Blinding can refer to at least four groups of people: those recruiting patients, the study participants themselves, those assessing the outcomes in study participants, and those analyzing the results [14]. The term “double blind” traditionally refers to a study in which both the participants and the investigators are “blind” to the study intervention allocation, but the term is ambiguous unless qualified by a statement as to who exactly was blinded.

**Box 9.2** Adequacy of generation and concealment of randomization sequence

#### Generation of the randomization code

- Adequate: random numbers generated by computer program, table of random numbers, flipping a coin.
- Inadequate: quasi-randomization methods (for example, date of birth, alternate records, date of attendance at clinic).

#### Concealing the sequence from recruiters

- Adequate: if investigators and patients cannot foresee the assignment to intervention groups (i.e., numbered and coded identical sealed boxes prepared by central pharmacy, sealed opaque envelopes).
- Inadequate: allocation schedule open for recruiting physician to view beforehand, unsealed envelopes.

Blinding is less of an issue with objective outcomes such as death, but it is especially important with subjective outcomes such as the opinion of participants or assessment of disease activity, as often happens in many dermatology trials. Blinding may be achieved by a range of techniques, such as ensuring that placebo tablets look, feel, smell, and taste the same as the active tablets [15], or, in the case of ointments, by using the same vehicle or base in which the active ingredient is formulated [16]. Even outcomes that may at first seem very difficult to blind – such as parents' views on the effects of laser treatment versus observation only for their child's hemangioma – can be blinded by taking digital images and then asking a panel of independent parents to judge the therapeutic response whilst concealing the identity of the intervention groups [17]. Judging whether a study has been truly blinded can be tricky and relies on a clear description in the methods section of the steps taken to ensure blinding, such as the use of placebos. Just because a study is described as being “double blinded” does not necessarily mean that blinding was achieved. For example, placebo-controlled RCTs of oral retinoids (which have predictable adverse effects of mucosal dryness in nearly all those given the active drug) are impossible to blind effectively, despite studies regularly referring to them as “double-blinded” [18]. The same applies to controlled trials of topical capsaicin, which creates a burning sensation when applied to the skin [19]. Some trials test the effectiveness of their blinding methods by asking study participants at the end of the study to guess which treatment they had been allocated to [16].

In many circumstances, blinding of the intervention is not possible. As an example, in an RCT of ion-exchange water softeners for atopic eczema, participants could not be blinded as they could guess whether they had a genuine or sham water softener due to increased soap suds production [20]. In such situations, it is essential that the primary outcome measure for the trial is an objective one such as examination of the skin by a research nurse blinded to the allocation status. In this trial, there was no evidence of a treatment effect for the objective outcomes determined by blinded nurse assessors, but some evidence of treatment effect for subjective reports from the unblinded participants, underlining the importance of blinded outcome assessments [20].

It is important to emphasize the difference between allocation concealment and blinding, although they may superficially appear to be the same. Failure to conceal the randomization sequence may result in groups that are unequal in terms of severity or prognostic factors and is a form of selection bias, whereas failure to mask the intervention once a fair randomization has taken place represents a form of detection or information bias. Both can result in an incorrect estimate of the effects of a treatment. Studies that are not double-blinded typically overestimate treatment effects by about 14% in comparison with studies that are double-blinded [8].

### Accounting for all those randomized

The whole point of randomization is to create two or more groups that are as similar to each other as possible, the only exception being the intervention under study. In this way, the additional effects of the intervention can be assessed [21]. A potentially serious violation of this principle is the failure to take into account all those who were randomized when conducting the final main analysis – for example, participants who deviate from the study protocol, those who do not adhere to the interventions, and those who subsequently drop out for other reasons. People who drop out of trials differ from those who remain in them in several ways [22]. People may drop out because they die, encounter adverse events, get worse

(or no better), or simply because the proposed regimen is too complicated for a busy person to follow. They may even drop out because the treatment works so well. Ignoring participants who have dropped out in the analysis is not acceptable, as their very reason for dropping out is likely to be related in some direct or indirect way to the study interventions. Excluding participants who drop out after randomization potentially biases the results. For example, in a study of emollients for atopic eczema, the authors chose to only report the results of patients who did well and excluded patients who did poorly, thereby giving a more favorable impression of the treatment effect [23]. One way to reduce bias is to perform an ITT analysis, in which all participants initially randomized are included in the final analysis [22,24].

Unless one has detailed information on why participants dropped out of a study, it cannot be assumed that an analysis of those remaining in the study to the end is representative of those randomized to the groups at the beginning. Failure to perform an ITT analysis may inflate or deflate estimates of treatment effect [9]. Performing an ITT analysis is often regarded as a major criterion by which the risk of bias of an RCT is assessed.

It may be entirely appropriate to conduct an analysis of all those who remained at the end of a study (a “per protocol” analysis) alongside the ITT analysis, especially in trials that are designed to show therapeutic equivalence or noninferiority [25]. Discrepancies between the results of ITT and per-protocol analyses may indicate the potential benefit of the intervention in ideal compliance conditions and the need to explore ways of reformulating the intervention so that fewer participants drop out of the trial. Discrepancies may also indicate serious flaws in the study design. A good discussion of when and where it might be appropriate to exclude trial participants from the main analysis may be found elsewhere [26].

### Declaring and presenting the primary outcomes

Many trials report as many as 10 different outcome measures recorded at several different time points. Even by chance, at least 1 in 20 of such outcomes will be “significant” at the 5% level. It is therefore important to ensure that trialists of studies that use many outcomes are not data dredging. By data dredging, I mean performing repeated statistical tests for a range of outcome measures and then emphasizing only the one that “looks good” and that is statistically significant at the “magic” 5% level. Such a practice is akin to throwing a dart and drawing a dartboard around it. Instead of distorting evidence in this way, trialists should declare up front what they would regard as a single “success criterion” for a particular trial (i.e., the primary outcome measure). This way, the results are more credible if that main success criterion is fulfilled – as opposed to some secondary or tertiary outcome measure that turns out to be “significant” at one particular assessment time point.

In addition to data dredging in order to *highlight* the outcomes that look best, the phenomenon of selective reporting of outcome measures can also result in the deliberate *omission* of some outcomes that were part of the original study protocol. The issue of outcome reporting bias has been well documented by Chan and Altman in 519 trials with 553 publications relating to 10557 outcomes identified in trial protocols [27]. Chan, a dermatologist, found that on average, 20% of the outcomes measured in parallel group studies were incompletely reported, and that such incompletely reported outcomes had higher odds of being nonsignificant in comparison with fully reported outcomes (odds ratio 2.0; 95% confidence interval, 1.6 to 2.7). The medical literature, therefore, represents a selective and biased subset of study outcomes. Selective

**Table 9.1** Trial reporting and study quality may be related but are not necessarily the same. All poorly reported trials reside in the shaded area of uncertainty.

Reporting quality	Study quality	
	Good	Flawed
Clear	May be helpful for clinical practice.	At least you can tell it is flawed and make a judgment on utility.
Poor	A sparkling diamond – but how do you know?	Difficult to distinguish from a good but poorly reported study.

Source: Williams, 2010 [33]. Reproduced with permission from Biomed Central Ltd.

reporting outcome bias can be lessened by ensuring that all RCT protocols are registered in a publically accessible site and that the protocol includes a description of the main outcome measures [27–30]. In dermatology, one study of 109 RCTs on atopic eczema published between 2007 and 2011 found that only around one-third had been registered on an approved public register, and that only five trials provided enough information to be confident that reported outcomes were the same as the original registration [31].

**Quality scales**

Although space in journals has sometimes been suggested as a reason for not including vital information such as sample size calculation that could be found in original study protocols, it has been shown that faulty reporting generally reflects faulty trial methods [8,11,32]. The relationship between trial reporting and trial quality is illustrated in Table 9.1 [33].

A number of scales have been developed for assessing study trial quality over the past 20 years. These vary in the dimensions covered and in their complexity [7]. Generally, the recent trend has been to use the few quality criteria suggested in Box 9.1, plus a few more that the appraiser considers important in relation to the condition and question being studied [8]. It is now considered unwise to use summary quality scores in an attempt to “adjust” the potentially biased treatment estimate, because the effects of such adjustment vary with the scale used and the way in which the components of each scale are weighted [34]. Instead, greater emphasis is placed on using the *components* of the scale as The Cochrane Collaboration risk of bias tool, and then to consider how each aspect may affect the results [8,10].

**Additional empirical criteria**

**Disease definition**

Whereas it may seem simple to assess the four components of randomization generation/concealment, blinding, accounting for all those randomized with an ITT analysis, and comparing a trial protocol with what was eventually published in order to assess selective reporting outcome bias, other topic-specific items may need to be assessed in order to make sense of the value of a particular RCT. The influence of such disease-specific factors in dermatology is an area that requires further systematic research.

A clear description of the disease being studied may be important. For example, when referring to a child with atopic eczema/dermatitis, I would not trust a study that claimed a beneficial effect for a new treatment if the study included both children and adults with diverse eczematous dermatoses [35], as people with such conditions might respond differently [36]. And if the study did refer to atopic eczema/dermatitis, I would like to see a clear description of

how the disease was defined. Even disease subgroups may need to be defined – for example, a study seeking to reduce atopic eczema severity by reducing house mites might make little sense unless those included were shown to be sensitive to house dust mites in the first place.

**Similarity of groups for baseline differences**

In addition to helping to balance for the *known* predictors of treatment response, such as baseline disease severity (which could serve as confounders when evaluating treatment efficacy between groups), it has also been suggested that randomization will balance against unknown confounders [8]. This statement is superficially appealing, but is difficult to verify if these confounders are indeed unknown. Yet simple randomization, even when perfectly implemented on small sample sizes, may still result in imbalances in possible cofactors that can affect the treatment response. In other words, randomization is not a guarantee against imbalance, although more sophisticated methods of randomization, such as blocking, minimization, and stratification, can help minimize such imbalances [14].

It is quite common for the first table in the results section of an RCT report to show a long list of demographic characteristics of the participants in the different treatment groups, along with a statement to the effect that “the two groups did not differ statistically at baseline” [37]. Such a statement is problematic for two reasons:

- It is inappropriate to perform such multiple statistical tests without prior hypotheses – indeed, many of the variables recorded may be totally irrelevant to predicting treatment response.
- There may still be no arbitrary 5% statistically significant differences even for gross imbalances in treatment groups, simply because the groups are so small; that is, failure to demonstrate statistically significant differences between the groups may be related to lack of power.

Before reading such tables, the most important thing to do is to ask oneself beforehand, “What are the most important factors that may predict the treatment response?” and then to see whether they have been recorded. If there are major imbalances, such as in the baseline severity score, then these can and should be allowed for in a number of ways during analysis – for example, with a multivariate analysis adjusting for baseline severity as a covariate [14].

**“Sensible” outcome measures**

In evaluating a clinical trial, look for clinical outcome measures that are clear-cut and clinically meaningful to you and your patients [38]. For example, in a study of a systemic treatment for warts, complete disappearance of warts is a meaningful outcome, whereas a decrease in the volume of warts is not [39]. The development of scales and indices for cutaneous diseases and testing their validity, reproducibility, and responsiveness has been generally inadequate but is receiving more attention [40–42]. A lack of clearly defined and clinically useful outcome variables remains a major problem in interpreting clinical trials in dermatology. Usually, dermatology clinical trials need to include at least four outcomes: a patient-centered outcome that seeks the views of trial participants on the “success” or otherwise of the study treatments; an objective and validated outcome measure of treatment benefit that has not been tampered with; a measure of harm; and a validated quality-of-life scale.

Until better scales are developed, trials with the simplest and most objective outcome variables are probably the most useful.

Categorical outcomes are usually widely understood by clinicians and patients alike. Thus, trials in which a comparison is made between death and survival, patients with recurrence of disease and those without recurrence, or patients who are cured and those who are not cured are studies whose outcome variables are easily understood and verified. For trials in which the outcomes are less clear-cut and more subjective, a simple ordinal scale is probably the best choice. The best ordinal scales involve a minimum of human judgment, have a precision that is much smaller than the differences being sought, and are sufficiently standardized to enable others to use them and produce similar results [38,43]. There is currently an emphasis throughout the field of medicine to develop core outcome sets for clinical trials of a particular condition, an approach pioneered by the Outcome Measures in Rheumatology group (<http://www.omeract.org/>) and now encouraged by the international Core Outcome Measures in Effectiveness Trials group (<http://www.comet-initiative.org/>). In the field of dermatology, core outcome sets are being established, such as the Harmonising Outcomes for Eczema group (<http://www.homeforeczema.org/>), which has used international consensus techniques informed by evidence reviews to identify the four key domains that should always be measured in atopic eczema/dermatitis RCTs [44].

### Doing the wrong tests

It is quite common for continuous data such as acne spot counts to have a skewed frequency distribution. It may then be inappropriate to use parametric tests such as the Student *t*-test without first transforming the data. Alternatively, nonparametric tests that do not rely on the assumption of a normal distribution can be used. A quick way to check whether a continuous variable is normally distributed is to determine whether the mean minus two standard deviations is less than zero. If it is, the data are likely to be skewed. Continuous data are typically underspecified in terms of analyzing and presenting the full range of data in RCT reports [45].

### Testing the wrong thing

Performing a statistical test on something other than the main outcome of interest is a subtle but not uncommon error in dermatology trials [46,47]. When comparing a continuous outcome measure such as a decrease in acne spots between treatment A and treatment B, the correct summary statistic to challenge the null hypothesis of no difference between the treatments is to examine the *difference between the two treatments* in terms of the change in the spot count from baseline. Sometimes the investigators simply perform a statistical test on whether the acne lesion count falls from baseline in the two groups independently. If the fall in spot count reaches the 5% level in one group but not in the other, then the authors may conclude that “therefore treatment A is more effective than treatment B.” Perhaps the *P* value for change in spot count from baseline is 0.04 in one group (i.e., significant) and 0.06 in the other (i.e., conventionally nonsignificant). This practice is clearly inappropriate, since the difference *between* the two treatments has not been tested.

### Interpreting trials with negative results

Misinterpreting trials with negative results is a common error in dermatology clinical trials [48]. Failure to find a statistically significant difference between treatments should not be interpreted as showing that “treatment is ineffective.” Put another way, no evidence of effect is not the same as evidence of no effect [49]. In many dermatology trials, the sample sizes are much too small to detect

clinically important differences. Providing 95% confidence intervals around the main response estimates allows readers to see what kind of effects might have been missed. For example, in an RCT of famotidine versus diphenhydramine for acute urticaria, itch as measured by a 100 mm visual analog scale decreased by 36 mm in the famotidine group and by 54 mm in the diphenhydramine group, a difference of 18 mm (54 mm – 36 mm) in favor of diphenhydramine. Although the statistical test for this difference of 18 mm between the two treatment groups was not significant at the 5% level, there was a clear hint of a greater reduction in itch in the diphenhydramine group. The 95% confidence interval around the 18 mm difference between the groups was from –3 to 38 mm. In other words, the results were compatible with a difference of as little as 3 mm in favor of famotidine and as much as 38 mm in favor of diphenhydramine [50].

### The trial environment

Once randomized, it is important that the two intervention groups are followed up in similar ways. Previous studies have shown the nonspecific benefits of being included in a clinical trial, even in placebo groups [51]. Part of the benefit might be the result of better ancillary care and motivation prompted by frequent follow-ups and being “fussed over” by study assessors, a phenomenon known as performance bias [14]. Performance bias can be particularly problematic for talking therapies that involve groups compared with individual standard care, where it can be difficult to say whether the additional benefits found are due to the specific talking therapy or the extra attention afforded to those taking part in groups. It is important, therefore, to scrutinize whether the treatment groups have been treated equally in terms of the frequency and duration of follow-up and whether they have been afforded identical privileges except for the treatment under investigation. For chronic diseases such as atopic eczema, it is important to see whether additional “rescue” therapies are used that could confound the true difference between competing treatments. Recording and presenting data for co-treatments and adjusting for them are ways of evaluating their impact. Sometimes, especially in surgical trials, the effects of the expertise of the surgeon or center undertaking the procedure can result in an unfair estimation of treatment effect – a phenomenon that can be overcome by ensuring that participants are randomized to clinicians who are expert on delivering the intervention or by adjusting for “center effects” [52,53].

### Sponsorship issues

It is natural to assume that authors of a clinical trial of a dermatological drug that has taken years of development investment by a pharmaceutical company will strive to demonstrate that the drug is successful. Indeed, millions of dollars of profit may rely on convincing opinion leaders in dermatology of a new drug's worth. Yet the influence of sponsorship on efficacy claims has not been adequately explored in dermatology RCTs. Drug companies and trialists have many opportunities to influence journal readers when the results of their trial are published (Box 9.3).

Conflicts of interest are not unique to the pharmaceutical industry, although some of the best examples of distorting the scientific record have emerged from company-sponsored studies [54]. Those conducting trials for government agencies, for example, might have a vested interest in wishing to show that a new drug is less cost effective than standard therapy. Some independent clinicians with preformed conclusions about an existing treatment may be equally susceptible to being influenced by their own prejudices when

**Box 9.3** Ways to enhance the impact of positive studies or reduce the impact of negative studies

- Withhold “negative” trials from being published at all by keeping them as “data on file.”
- Delay release of such “negative” studies into the public domain.
- Stopping a trial early at a “random high.”
- Publish negative studies in an obscure or non-English-language journal.
- Deliberately select outcome measures that show the treatment in a better light – for example, Psoriasis Area and Severity Index (PASI) 50 instead of PASI 75.
- “Torture” the data by performing multiple statistical tests on subgroups.
- Use many statistical techniques until you find one that shows the results in the best light.
- Divert attention from the main “negative” findings by emphasizing biomedical markers and a mechanism of action smokescreen.
- Incorrectly interpret inconclusive studies as equivalence studies – for example, by suggesting that two drugs are the same when the confidence intervals surrounding their differences are large.
- Use a comparator that other studies have not used in order to avoid a head-to-head comparison with a current established treatment.
- Use the comparator drug at the wrong dose or frequency to show the active drug in a better light.
- Avoid mentioning significant adverse events in the abstract and discussion sections.
- Flood the literature with lots of placebo-controlled studies that make the new drug look impressive. Few doctors use placebos in clinical practice, and most would like to know how a new drug compares with the best existing active therapy.
- Use optimistic language and writing styles when discussing essentially negative studies – for example, repetition of positive results such as “nonsignificant trend in favor of,” or use percentage relative treatment benefits when the absolute degree of improvement is small.
- Publish positive study results in duplicate or triplicate – overtly or even covertly.

testing and writing up the results for that treatment. In assessing a study, readers should always consider who sponsored the study and ask themselves whether such sponsorship could have influenced the results or the way that they are presented. Empirical research from general medicine trials suggests that inclusion of a clear statement of pharmaceutical sponsorship does influence a clinician’s interpretation of results. Absence of declared sponsorship may not mean absence of sponsorship [55].

### Other factors

This short chapter can only touch on some of the bigger issues in interpreting clinical trials. For most of the chapter, I have referred to single pharmacological interventions. Other more complex interventions, such as educational classes for eczema families, consist of several defined components, such as the educational package itself, who delivers it, how it is delivered and reinforced, and so on, and may require additional special interpretation [56]. Guidance on the evaluation of RCTs of complex interventions is discussed elsewhere [57,58]. Trials are often divided into those that are explanatory and measure efficacy (can this intervention work under ideal trial conditions?) or pragmatic and measure effectiveness (how well does this intervention work when used under typical conditions?) [59], whereas in reality they lie on a pragmatic–explanatory continuum [60,61]. The reader is referred to other resources to learn more about variations in study design, such as adaptive designs, crossover studies, or internally controlled right/left limb studies, which are frequently used in dermatology [62].

Issues on the unit of randomization are relevant to some areas of dermatology, where the failure to consider the whole person as opposed to number of warts can have a distorting effect on trial conclusions [63].

### Attempts to overcome limitations in the conduct, reporting, and publication of clinical trials

At this point, the reader might despair at the many hazards in interpreting clinical trial reports and in the way that they have been published over the years. But nearly all of the issues described can and have been overcome by strict reporting guidelines and the compulsory registration of clinical trials. The need for better standards of reporting of trials have led to the Consolidated Standards of Reported Trials (CONSORT) statement, which was updated in 2010 [64]. CONSORT contains a structured checklist for reporting the details of clinical trials, including methods of randomization and concealment, blinding, ITT analysis, and a flow diagram to illustrate the progress of trial participants. Several dermatology journals now require that submitted clinical trial reports meet CONSORT standards in order to be published [28,65–67].

Whereas CONSORT may help with better reporting of trials that find their way into the public domain, it does not overcome the pervasive effect of publication bias [68]. The creation of prospective clinical trial registers accessible in the public domain is becoming a powerful tool to ensure that *all* trials are eventually published in some form, or at least that their presence can be determined by those doing systematic reviews of all available evidence [28–30]. Trial registers with fully accessible study protocols minimize publication bias, data dredging, and outcome reporting bias and reduce research wastage [69]. Publishing trial protocols in the public domain may also minimize the increasing problem of covert ghost authorship writing, which may occur in up to 75% of industry-sponsored trials [70]. Thankfully, several leading dermatology journals now require RCTs to have been registered in accordance with the International Committee of Medical Journal Editors statement [28,29,67]. The World Health Organization International Clinical Trials Registry Platform (<http://www.who.int/ictcp/en/>), holds an up-to-date record of trials registries that contain an internationally agreed set of information conforming to World Health Organization standards.

# Assessing and explaining the evidence on harms of medical interventions

**Luigi Naldi**

Centro Studi Gruppo Italiano Studi Epidemiologici in Dermatologia, Department of Dermatology, Ospedali Riuniti, Bergamo, Italy

## Introduction

Like other human activities, medical interventions can carry a risk of unintended adverse events. Whenever a drug is prescribed, it can potentially cause an adverse reaction. Despite limited accurate data, a widely cited meta-analysis of 39 prospective studies in US hospitals performed from 1966 to 1996 found an incidence of severe adverse drug reactions (i.e., life-threatening or prolonged hospital stay), among inpatients, of 6.7% and 0.32% deaths [1]. Despite these impressive figures, the rate of severe adverse reactions for any given drug is usually low. In addition, the system works in such a way that even a small increase in the incidence of a clinically severe reaction may prompt the withdrawal from the market of the implicated drug.

It is commonly stated that clinical decisions should balance the benefit with the risk, or more properly the harm, of the available options. A difficulty stems from the fact that data on benefits and harms of medical interventions are usually derived from different study designs and information sources. Our discussion focuses largely on the safety of drug use. While systems to survey the safety of medications are well established, that is not the case for other medical interventions (e.g., surgical procedures, invasive diagnostic tests). It is well accepted that no in vitro or animal models can accurately predict adverse events associated with a drug before it is used in humans. Advances in understanding of the causation of adverse reaction (e.g., pharmacogenomics) may one day make it possible to predict harms in individual patients more reliably [2,3]. An example of the way pharmacogenomics could influence the identification of high-risk people is provided by the association of Stevens–Johnson syndrome and toxic epidermal necrolysis with specific human leukocyte antigen haplotypes [4–8].

## Data sources

### The limitation of randomized clinical trials

Randomized clinical trials (RCTs) are very good for providing an unbiased estimate of treatment effect by controlling not only for determinants of outcome we know about, but also for those we do not know about. If RCTs demonstrate an important relationship

between an agent and an adverse event, then we can trust the results. However, RCTs are usually designed to document frequent events; that is, those associated with the intended effect of a treatment. With the usual sample size, which rarely exceeds a few thousand people, RCTs cannot accurately measure the frequency of uncommon events [9,10]. Besides the statistical power issue, additional limitations include the usual short duration of most clinical trials and the careful selection of the eligible population (restriction in patient selection according to age, co-morbidity, etc.). All in all, when an intervention has been proved effective in an RCT, its safety still remains to be established. At the very best, pharmaceutical companies may strive to work out the adverse effect profile of a drug before licensing, but because only a limited number of selected individuals can be exposed to the drug before it is released, only common adverse events can be accurately documented and the complete range of adverse events is left to emerge later. This is particularly true for delayed reactions and rare, but severe, acute events.

### The value of suspicion: case reports and case series

Unlike RCTs, individual cases or case series provide no comparison with a control group and cannot produce reliable risk estimates. Despite their limitations, astute clinical observations are still essential for describing new disease entities and raising new hypotheses concerning disease causation, including the effects of medical interventions [11]. Case reports remain a first-line modality to detect new adverse reactions after a drug has been marketed [12]. Spontaneous surveillance systems, like the International Drug Monitoring Programme of the World Health Organization (WHO), capitalize on the collection and periodic analysis of spontaneous reports of suspected adverse drug reactions [13]. All physicians and other health workers and also patients are expected to take an active part in promoting the safety of medical interventions and to contribute by reporting any suspected adverse events they observe in association with drug use [14]. Collections of reported adverse events may be explored to raise signals (Table 10.1) to be validated by more formal study designs; that is, studies providing estimates of incidence rates and quantifying risks [15,16]. Spontaneous

**Table 10.1** Criteria for signal assessment in spontaneous surveillance systems.

1	Number of case reports
2	Presence of a characteristic feature or pattern and absence or rarity of converse findings
3	Site, timing, dosage-response relationship, reversibility
4	Rechallenge
5	Biological plausibility
6	Laboratory findings (e.g., drug-dependent antibodies), data from animal toxicology
7	Previous experience with related drugs

reporting should be seen as an early warning system for possible unknown adverse events; it is prone to many kinds of bias [17]. Case reports may be more effective in revealing unusual or rare acute adverse events. In general, they do not reliably detect adverse drug reactions that occur widely separated in time from the original use of the drug or that represent an increased risk of an adverse event that is common in populations not exposed to the drug. One concern with spontaneous reporting systems is that they are hindered by low reporting rates, and when adverse reactions are reported the information is of variable quality.

### Epidemiological studies: the most comprehensive source of data

Quantitative estimates of harms associated with drug use may be obtained from analytic epidemiology studies – that is, cohort and case-control studies [18] – and from a number of modifications of these traditional study designs pertaining to the broad area of pharmacoepidemiology (Table 10.2). These observational (nonrandomized) studies are prone to unmeasured confounders and biases and provide less-stringent results than RCTs. On the other hand, in the “real world,” these study designs may represent the only practical way of obtaining risk estimates once a new drug has entered the market. Cohort studies are studies where groups are defined according to the exposure status (e.g., users and nonusers of a drug) and are followed up with subsequent events being recorded and compared [19,20]. In contrast, case-control studies are studies where groups are defined according to their experience of an outcome of interest (e.g., cases of toxic epidermal necrolysis and their adjacent controls) and prior exposures are ascertained retrospectively and compared [21]. A crucial point for the validity of a case-control study is the choice of appropriate controls. In principle, controls should be an unbiased sample of those individuals composing the so-called “study base.” Controls for cases arising in the ambulatory population with resultant hospitalization (community cases) may be represented by patients admitted to the same hospitals as cases for an acute condition or for an elective procedure not suspected of being related to drugs [22].

Generally speaking, cohort studies are better suited to the study of rare exposures and common events, and case-control studies to the assessment of rare outcomes and relatively common exposures. In addition, while cohort studies allow the assessment of several outcomes for one specific exposure, case-control studies can assess the role of a range of different exposures on the development of a single, specific outcome. Cohort studies are not feasible when dealing with rare events, because millions of drug users have to be observed for years. In these conditions, case-control studies with a very large population base are the most feasible methods. For example, intuitively, only a case-control study would be feasible to assess the pharmacological risk for a disease like toxic epidermal necrolysis with an expected rate in the general population of one case per million people per year [23,24].

**Table 10.2** Examples of pharmacoepidemiologic methods.

- Intensive hospital monitoring
- Prescription-event monitoring (PEM)
- Cohort studies (linked or not to registries)
- Case-control studies and case-control surveillance
- Case-crossover design
- Nested case-control studies
- Record linkage

**Table 10.3** Measures of association.

Patients	Adverse event (cases)	No adverse event (controls)
Exposed	<i>a</i>	<i>b</i>
Not exposed	<i>c</i>	<i>d</i>

Relative risk =  $[a/(a + b)]/[c/(c + d)]$ .

Odds ratio =  $(a/c)/(b/d)$ .

Excess risk =  $[a/(a + b)] - [c/(c + d)]$ . Excess risk may be also referred to as the “risk difference” or the “absolute risk reduction.”

NNT =  $1/\text{Excess risk}$ .

NNT from case-control studies =  $1/[(\text{Odds ratio} - 1)(\text{Unexposed event rate})]$ .

It is important to measure outcome and exposure in the same way in the groups being compared in observational studies. On the other hand, even if investigators document the comparability of potential confounding variables in the groups being analyzed (exposed and nonexposed cohorts, or cases and controls) or use statistical techniques to adjust them, there may be an important imbalance that the investigators do not know about or simply have not measured that may be responsible for any observed difference. This is the main limitation of observational studies compared with RCTs. It is usually considered that such analytical studies should be developed with the aim of testing a specific predefined hypothesis. In the last few decades, modifications of traditional cohort and case-control studies have been developed to explore new associations and to raise signals. Record linkage is based on linkage of data on exposure and outcome from large electronic databases, while case-control surveillance is the ongoing collection of cases of pre-specified rare and severe acute events and of suitable controls to look for new associations of the events with drug exposure [25].

The association of an exposure with a given event is usually expressed in terms of a relative risk or odds ratio (an estimate of the relative risk obtained from case-control studies) (Table 10.3). The relative risk is a measure of the size of an association in relative terms. It refers to the ratio of the incidence of the outcome among exposed individuals to that among nonexposed. Values  $>1$  represent an increase in risk associated with the exposure, while values  $<1$  represent a reduction in risk. A relative risk of 2, for example, tells us that the event under study occurs twice only in the exposed people as in nonexposed. For rare events, even a large relative risk may translate to the occurrence of a few additional drug reactions. The total incidence of an outcome among exposed persons is a combination of the baseline incidence plus the excess of incidence due to the exposure. The excess risk (or risk difference or absolute risk reduction) is calculated as the difference between the incidence among exposed individuals and the incidence among nonexposed individuals. It measures the occurrence of an outcome among exposed individuals that can be attributed to the exposure. As such, it is a better measure of the impact of different outcomes than the relative risk, and a more informative measure from a physician's and a public-health point of view. Measures of excess risk are directly calculated in cohort studies and, provided that data on the

incidence of the outcome are available in the underlying unexposed population, they can also be derived from case–control studies.

### A trend toward changing the surveillance paradigm: proactive pharmacovigilance

In recent years, the progression of evidence from unsolicited case reports to more formal epidemiological studies has been partly blurred by the emergence of the concept of “proactive pharmacovigilance,” which involves the a-priori identification of important areas of uncertainty about safety and the implementation of studies aimed at reducing these uncertainties, ideally as soon as a drug has entered the market [26]. One example of such an attitude is the already mentioned mechanism of case–control surveillance where rare and severe acute events frequently associated with drug use are examined for their associations with specific etiologic candidates via a case–control design [25]. Another example involves data mining and signal detection by scanning large databases that may be interconnected (record linkage) [27]. A further example is offered by population-based treatment registries, where registration and follow-up of patients being prescribed predefined drugs of interest occur [28]. If organized in a similar way, data from registries considering the same drugs could be merged to obtain summary estimates of risks for adverse events of interest [29,30]. Recently, the European Medicines Agency introduced Risk Management Plans, and is promoting proactive pharmacovigilance with the development of the European Network of Centres for Pharmacovigilance and Pharmacoepidemiology [31].

### Back to the individual patient

What is the risk of extraspinal hyperostosis in a psoriasis patient treated for several months with acitretin? Does psoralen+UVA therapy increase the risk of non-melanoma skin cancer in a patient being treated for mycosis fungoides? What is the chance of severe depression in an adolescent on 13-*cis*-retinoic acid for acne? To address these questions, physicians must effectively search for evidence and be able to assess the validity of the available data, to consider the strength of any documented association, and its relevance to an individual patient [32].

We have already noted that many different sources of information should be looked for and the search should not be limited to RCTs [33]. When data from RCTs are scrutinized, the statistical power to rule out any important adverse event should be taken into account. When dealing with observational studies, it should be carefully considered if they provide reliable quantitative risk estimates or simply generate signals needing further validation. The optimal study design should be one assuring unbiased comparison between exposed and unexposed groups. Comparison groups should be similar with respect to important determinants of outcome. Outcome and exposure should be measured in the same way in the groups being compared, and the exposure should clearly precede the adverse outcome. In addition, follow-up should be sufficiently long and complete and the study should have enough statistical power to document the association of interest.

When risk estimates from several studies are available, are they roughly in the same direction or are they consistent? If not, reasons for the discrepancies should be looked for. Systematic reviews may help to summarize the study results [34]. Unfortunately, meta-analyses of observational studies are of less value than those of RCTs [35]. Once an association has been established, the magnitude of the risk should be taken into account and expressed in

**Table 10.4** Discussing benefits and harms with patients, and monitoring treatment.

- 1 Start with the aims of treatment, for each option considering specific benefits and harms, their intensity and likely duration, how likely they are to occur, and what we do not know about it
- 2 Find out how much the various possible outcomes matter to the patient
- 3 Jointly make the choice, decide when and how to follow up and review the treatment, and what you will want to know then
- 4 Consider when to change the dose, and how to decide when to stop the drug
- 5 Monitor treatment over time, asking a few questions:
  - How is the patient using the drug?
  - Is it still needed? Is it still working sufficiently?
  - What does the patient say about the drug?
  - Has anything unexpected happened? Might it have to do with the drug? If so, consider reporting it (by relying on local spontaneous reporting system)

Source: Herxheimer, 2005 [39].

understandable terms if they are to help clinicians. We have already noted that, from the perspective of a physician, the excess risk (or risk difference) is more informative than the relative risk. In the context of RCTs, Sackett and co-workers proposed a method for converting risk differences into a more intuitive quantity, *the number needed to treat* ( $NNT = 1/\text{excess risk}$ ) [36]. It is the number of people who must be treated in order that one clinical event is prevented by the treatment at issue (e.g., the number of people to be treated to avoid one patient experiencing a relapse of psoriasis). The “number needed to harm” (NNH) or “number of patients needed to be treated for one additional patient to be harmed” (NNTH) [37] is the number of people exposed to a given treatment such that, on average and over a given follow-up period, one additional person experiences an adverse effect of interest because of the treatment. In RCTs and cohort studies, NNH is directly calculated as the reciprocal of the excess risk. Recently, a formula has been proposed using odds ratios from case–control studies and data on the event rate in the unexposed population (Table 10.3) [38]. According to the formula, giving an odds ratio of 3 and unexposed event rate of 1 per 1 000 000 people, the NNTH can be calculated as 500 000 (i.e., 500 000 people to be treated to experience one additional adverse effect with the treatment).

After deriving estimates for the potential harm of an intervention, they should be weighed against the expected benefits of the same intervention. The adverse consequence of not withholding the possible harm from using the intervention should be carefully considered. A final decision should try to integrate probability issues with the patient’s values and preferences about therapy. This requires patient education about the benefits, possible harms, and risks of alternatives tailored to the particular patient’s risk profile and communication skills by physicians [39].

To conclude, not only should physicians be able to retrieve and critically assess the evidence on the safety of any given intervention, but they should actively promote safety by contributing to surveillance programs once an intervention is proposed to the medical community, and should be able to effectively communicate benefit and harms to individual patients, enabling them to share therapeutic decisions and improving treatment adherence and effectiveness (Table 10.4).

# How to evaluate diagnostic tests

Joerg Albrecht<sup>1</sup> and Michael Bigby<sup>2</sup>

<sup>1</sup>Department of Medicine and Division of Dermatology, John Stroger Hospital of Cook County, Chicago, IL, USA

<sup>2</sup>Department of Dermatology, Harvard Medical School and Beth Israel Deaconess Medical Center, Boston, MA, USA

## Introduction

Every patient encounter involves a diagnostic process that establishes, confirms, or refutes a diagnosis. In some cases in dermatology this process is often simply examination of the skin. In other cases dermatologists use the full range of diagnostic tests available in medicine to confirm or establish a diagnosis. Within this range of options the choice of diagnostic tests depends on many factors, including:

- 1 the relative likelihood of the competing diagnoses;
- 2 the seriousness and therapeutic implications of the alternative diagnoses (e.g., is there a diagnosis that may be unlikely, but serious enough that it cannot be missed?);
- 3 the costs, toxicity, and difficulty of treatments;
- 4 the ability of distinguishing among the diagnoses with the diagnostic tools available;
- 5 the price and availability of the test;
- 6 the risks and discomforts associated with the test.

Tests are used when it is expected that the test can differentiate between the diseases in question. For example, a biopsy may not be used to distinguish between most generalized viral and drug eruptions because the histopathology of both entities is very similar. Instead, the history of concurrent symptoms or of recent drug exposure may lead to a diagnosis or suggest that viral titers be drawn. Ideally, a test will either confirm a diagnosis and lead to initiation of treatment, or exclude it.

## Critical appraisal of diagnostic studies

### Quality of evidence

To be valid, studies of diagnostic tests should have certain minimum features (Table 11.1). The test should be compared with a criterion or “gold” standard and the comparison should be blinded. The criterion standard needs to be consistently applied, and the study has to be conducted in an appropriate population. More detailed but important information that needs to be reported in studies evaluating tests has been published and will be helpful to assist the informed reading of the literature [1,2].

Studies reporting diagnostic tests in dermatology should adhere to established international reporting standards [1,2]. Studies of

diagnostic tests are prone to bias like other trials, but the type of design-associated flaws that influence performance characteristics is different from therapeutic trials. Many of these problems stem from the need to subject all patients to an often invasive or expensive gold standard in order to establish a diagnosis. Failure to do so in a wide range of patients often leads to overestimation of the test’s accuracy because, even for those patients for whom the probability seems low, the gold standard test identifies cases that may have been missed by other tests [3].

As in all types of study design, the results of diagnostic studies depend significantly on the population that is studied. A relevant group of patients and adequate population to study a test is defined based on the similarity of the spectrum of the disease in the study population to the population in which the test will be used. Reported performance measures of a test may differ by up to a factor of 3 in different clinical settings, depending on the patient case-mix (i.e., prevalence and severity of disease). This effect is called the spectrum effect [4]. Results from diagnostic studies cannot be generalized beyond the spectrum of the population that was studied.

Ideally, investigators should study a consecutively recruited population with a wide range of disease presentation. Many diagnostic studies, however, suffer from the problem that the gold standard is an invasive test (e.g., a skin biopsy). In order to avoid this test in patients who are not likely to have the disease, more severely affected patients are recruited and assessed. This recruitment bias may enhance the performance measures of the test, in that it skews the population toward a clinically obvious group.

Some investigators choose systematically not to subject patients with low probability and negative tests to the gold standard. These investigators will miss less obvious cases and overestimate the test performance. A variation of this is the differential verification bias, where a less rigorous reference standard is used for these patients. Test and reference standard need to be evaluated independently and blindly. Test accuracy may be overestimated by up to 30% if independent and blinded evaluation is not performed [4].

### Indices of test accuracy

The results of diagnostic studies are reported as one or more indices of test accuracy that describe the performance or operating characteristics of the test (Table 11.2). A highly specific test rules in the

diagnosis when positive, and a highly sensitive test can rule out the disease when negative. It is far from clear how high the sensitivity or specificity of tests has to be in order to reliably rule in or out a disease. Most authors would say greater than 0.95.

The positive and negative likelihood ratios, pretest probability, posttest probability, and threshold for action are important con-

cepts that must be understood to determine whether the results of a paper describing test characteristics are clinically relevant. The positive likelihood ratio is the percentage of people with the disease who have a positive test divided by the percentage of people who do not have the disease but who have a positive test. One way to calculate the likelihood ratio is sensitivity/(1 – specificity). The positive likelihood ratio estimates how much higher the likelihood of the disease is, given a positive test (posttest probability), compared with the probability before the test is done (pretest probability). Thus, it estimates the value of the test in informing the clinical decision.

The negative likelihood ratio is the index to calculate how much more likely a disease is going to be absent given a negative test. The likelihood ratio negative is the percentage of people with the disease

**Table 11.1** Quality of evidence in a study of a diagnostic test.

1. Independent, blind comparison with a reference (“gold”) standard of diagnosis
2. Evaluated in an appropriate spectrum of patients (like those in whom it would be used in practice)
3. Consistent application of the reference standard regardless of the diagnostic test result
4. Blinded evaluation of reference and test standard

**Table 11.2** Performance parameters for diagnostic tests. Source: Scott *et al.*, 2008 [3]. Reproduced with permission of Wiley.

		Target disorder		
		Present	Absent	Totals
Diagnostic test	Positive	A	B	A + B
	Absent	C	D	C + D
	Totals	A + C	B + D	A + B + C + D
Test characteristic	Alternative name	Question addressed	Formula and calculation	
Prevalence	Pretest probability	How common is the disease in the test population?	$(A + C)/(A + B + C + D)$ Patients with target disorder/all patients	
Sensitivity	True positive rate	What is the proportion of patients with the disease that have a positive test?	$A/(A + C)$ Patients with the target disorder and positive test/all patients with the target disorder	
Specificity	True negative rate	What is the proportion of patients without the disease who have a negative test?	$D/(B + D)$ Patients without the target disorder and a negative test/all patients without the target disorder	
Positive predictive value	Posttest probability of the disease with a positive test	What is the probability of the disease if the patient has a positive test?	$A/(A + B)$ Patients with a positive test and the disease/all patients with a positive test	
Negative predictive value	Posttest probability of health (no disease) with a negative test	What is the probability of no disease with a negative test?	$D/(C + D)$ Patients with a negative test and without the disease/all patients with a negative test	
Diagnostic accuracy		What proportion of all tests has given a correct result?	$(A + D)/(A + B + C + D)$ All patients positive test and with the disease (true positives) and all patients with a negative test who did not have the disease (true negatives)/all patients	
Likelihood ratio of a positive test (positive LR)		How much more likely is a positive test to be found in a patient with the disease than in a patient without the disease?	$[A/(A + C)]/[B/(B + D)]$ True positive rate/false positive rate, or [patients with positive test and disease/all patients with positive tests]/[patients with positive test without the disease/all patients without the disease], or rearranged to sensitivity/(1 – specificity)	
Likelihood ratio of a negative test (negative likelihood ratio)		How much more likely is a negative test to be found in a patient with the disease, than without the disease?	$[C/(A + C)]/[D/(B + D)]$ False negative rate/true negative rate, or [patients with a negative test with the disease/all patients with the disease]/[patients with a negative test and without the disease/all patients without the disease], or rearranged to (1 – sensitivity)/specificity	
Diagnostic odds ratio		How much more likely is the test to make a correct diagnosis than an incorrect diagnosis in patients with the disease?	Ratio of the positive likelihood ratio/negative likelihood ratio, or rearranged $(A \times D)/(B \times C)$	
Number needed to diagnose		How many patients have to be tested to give one correct positive test? (Primarily used for the evaluation of screening tests)	$1/\text{true positive rate} - \text{false positive rate} = 1/\text{sensitivity} - (1 - \text{specificity})$	

who have a negative test divided by the percentage of people who do not have the disease who have a negative test. The likelihood ratio negative is  $(1 - \text{sensitivity})/\text{specificity}$  and provides estimation of how much lower the likelihood of the disease is, given a negative (posttest probability), compared with the probability before the test is done (pretest probability). Whereas likelihood ratios concern the test performance in patients with or suspected to have the disease, the predictive values will assess the probability of the disease in patients with a positive test, or absence of disease in a patient with negative test (see Table 11.2 for details).

An ideal test is one that will almost always be positive when the disease is present and negative when the disease is absent. Thus, it has high sensitivity and specificity. Such a test would have a very high positive and a very low negative likelihood ratio [5].

However, even tests with good characteristics fail if the population being tested has a very high or very low prevalence of disease. A very specific test fails if used in groups of patients who have a very low probability of the disease. If there is little chance of finding a sick patient in a group, a very specific test may have a larger number of false positives than true positives. Similarly, a very sensitive test may have a seemingly large number of falsely negative results if used in a population with a high prevalence of disease. The lower the prevalence of disease in a tested population, the more confident we can be that a negative test indicates the absence of the disease, but the less confident we can be that a positive test indicates the presence of diseases. For example, in a group of 1000 healthy patients, a test with a specificity of 95% will identify 50 patients as diseased who are not diseased. Tests are most useful or predictive when the disease prevalence or pretest probability hovers around 50% [4].

Overuse of tests leads to follow-up tests and potentially overdiagnosis. While the costs to the health system associated with overtesting have been given some attention, the human costs in terms of disruption of life, anxiety, and risks associated with the tests are equally, or even more, important.

For the likelihood ratio to be useful, it is important to understand pretest probability, posttest probability, and threshold for action. Pretest probability is an estimate of how likely it is that the patient has the disease before the test is done. The pretest probability is based on available published data like the prevalence of the disease in a population, or based on physician experience and judgment. While prevalence data may give some indication, most testing in dermatology is based on clinical findings, which increase the pretest probability beyond the prevalence of the disease. Judgment, which may incorporate the likelihood of the competing diagnoses, is needed.

Once the pretest probability is known or estimated and the likelihood ratio is determined, a nomogram can be used to estimate the posttest probability (Figure 11.1). If the nomogram is not available, the calculations can be done manually, but require conversion of probabilities to odds. For a defined group of individuals or patients the odds of disease are defined as the probability of having the disease divided by the probability of not having the disease, or the probability divided by one minus the probability:  $\text{odds} = \text{probability}/(1 - \text{probability})$ .

For example, if in a similar group of patients the probability of a disease (or the proportion of people with the disease) is 0.60 (60%), the odds of the patients having the disease are  $0.60/(1.0 - 0.60)$ , or 3:2 (1.5) in that group. The posttest odds equals the pretest odds multiplied by the likelihood ratio. The formula  $\text{probability} = \text{odds}/(\text{odds} + 1)$  is used to convert odds back to probability. In our

**Figure 11.1** Nomogram for determining the post-test probability. To determine the post-test probability, draw a straight line through the pre-test probability and the likelihood ratio and read the post-test probability on the right.

example, if the patient has a positive test and the test has a likelihood ratio positive of 10, their posttest odds are 15 (15:1). The posttest probability of having the disease would then be  $15/(15 + 1) = 0.94$  or 94%.

Tests with likelihood ratios close to one are not likely to significantly change the posttest probability from the value of the pretest probability, since the pretest probability multiplied by one or a factor close to one results in a posttest probability of the same or nearly the same value. These tests are not helpful because they are unlikely to move the pretest probability above the threshold of action.

The threshold of action is the certainty that is needed to establish the diagnosis and act on it. The threshold of action depends on the clinical situation and the test. For clinically obvious and recurrent tinea pedis, for example, the threshold of action (i.e., prescribing a topical antifungal) will be low and the practitioner may decide to treat without performing any test. A negative skin scraping would not change the treatment decision in this case. For a patient suspected to have mycosis fungoides, however, a number of biopsies may be needed until a diagnosis is established, because histological confirmation is essential to establish this serious diagnosis. Thus, there are different thresholds for action for initiating treatment and making a diagnosis in different clinical situations.

### Applying evidence about a diagnostic test to the care of individual patients

The key questions to ask to determine whether the results of a diagnostic study can be applied to a specific patient are shown in Table 11.3.

**Table 11.3** Can you apply the evidence about a diagnostic test in caring for your patient?

- 
- Is the diagnostic test available, affordable, accurate, and precise in your setting?
  - Can you generate a clinically sensible estimate of your patient's pretest probability (from practice data, from personal experience, from the report itself, or from clinical judgment)?
  - Will the resulting posttest probabilities affect your management and help your patient? (Could it move you across a test-treatment threshold? Would your patient agree to the test and treatment?)
  - Would the consequences of the test help your patient?
-

<sup>2</sup>Department of Dermatology, Harvard Medical School and Beth Israel Deaconess Medical Center, Boston, MA, USA

## Introduction

Case reports and case series are often the first available evidence for the effectiveness of a treatment or for rare adverse effects of interventions. The British National Institute of Clinical Excellence (NICE) relies on evidence from case series in 30% of its reports that cover all fields of medicine. In spite of their methodological shortcomings, an analysis of case series in two areas relevant to NICE did not find that outcomes were better in the case series than in randomized controlled clinical trials of the same interventions [1]. Indeed, case series can generate high-quality evidence even without a documented control group, when the rates of events in a control group are likely to be near zero. This is most often the case when reporting of adverse events. These adverse events are not observed in the control group (e.g., those not taking medication) [2]. In our experience, the case reports and small series in dermatology have different characteristics and fairly often promote likely ineffective treatments with exaggerated conclusions [3]. However, they may remain the only evidence for the effectiveness of a treatment if controlled clinical trials are not available [4]. In dermatology, the most common reasons that controlled clinical trials may not be available are reasons of necessity, feasibility and of scale.

**Necessity.** The first and most obvious reason for lack of clinical trials is that treatments are so clearly effective that controlled clinical trials seem unnecessary (e.g., the use of insulin for type I diabetes) [5]. Such “all or none” treatments are acknowledged to have achieved the highest level of clinical evidence even without randomized clinical trials. All-or-none conditions are met when all or most patients died before the treatment became available, but some or many survived on treatment; or when some patients died before the treatment became available, but none or few died on it [6]. This “all-or-none” effect is exceedingly rare in dermatology, but the use of systemic corticosteroids in pemphigus vulgaris may fall in this category.

**Feasibility.** Studies that challenge the clinical perception of participants can be very difficult or impossible to conduct, because participation and recruitment of patients cannot be achieved. If therapies are strongly believed to work, there is most likely little interest to fund or conduct trials into their effectiveness. This state of affairs is unfortunate because the history of medicine is full of

reports of established practice that were ineffective or even harmful when subjected to clinical trials.

**Scale.** In dermatology there are treatments for more than 2000 syndromes or diseases. Many of these diseases are so uncommon that trials would have to be multicentered and very expensive. Finding funding for such studies on rare skin disorders to be conducted across several countries is often impossible, and pharmaceutical companies have almost no financial incentive to develop new drugs for rare diseases. Many treatments in dermatology are not very good and have low response rates which inflate the study sizes needed to demonstrate clinically meaningful and statistical differences. It therefore seems likely that many skin diseases and their treatments will never be subjected to clinical trials for pure questions of scale. In dermatology, the majority of diseases are unlikely to be the object of primary licensing trials. Thus, for a long period, or indeed forever, the only evidence for newly licensed drugs available comes in the form of case series or case reports. When reading this book it becomes obvious that for these reasons case series remain important clinical evidence in dermatology because they are often the only source of available evidence.

Recently, there has been renewed interest in the methodology of case reporting. Guidelines for the reporting of primarily therapy-oriented case reports have been developed and their publication as case reporting guidelines is imminent; this checklist should be helpful for authors and reviewers alike (J.J. Gagnier and D. Riley, personal communication, April 21, 2013). Another initiative has been the attempt to distinguish case series from cohort studies. The authors of a recent paper that separates the two designs argue that the difference between a case series and a cohort study is the ability of the latter to generate absolute risks [7]. Based on this assessment, the authors define case series as outcome based. By this definition case series are investigations in which patients with a certain outcome and a usually common exposure (disease or intervention) are described. Another type of case series is the description of a number of patients with their clinical characteristics, either as a prevalence study to describe or as a series of incidence cases in rare diseases. This separation of case series from cohort studies based on their statistical utility is intuitively convincing. It is also correct that the small number of case series cannot be the sole

distinguishing factor from cohort studies from a methodological point of view, but this differentiation creates the new problem that the number of cohort studies becomes inflated. It now includes often haphazard collection of poorly described individual cases that populate the literature. The authors acknowledge this problem and reasonably point out that the calculation of risks is not wise, even if it is possible, in a poorly conducted or reported cohort study. For therapeutic studies, they point out that a comparison group is almost always needed. We will avoid this differentiation; rather, in this chapter, we will focus on case series that may have many of the characteristics of cohort studies, but are either too small to calculate risks with confidence intervals small enough to be meaningful or too poorly reported to make use of statistics a good idea. In our opinion, this group covers the overwhelming majority of what has been traditionally thought to be case series in dermatology.

## Methodology of case series

Some characteristics of good case series are traditional methodological features associated with clinical trials (Table 12.1). In general, as for clinical trials, it is essential that the report allows full understanding of what happened to the patients. The ideal case series for the reader is one which constitutes an uncontrolled clinical trial and is ideally preplanned with blinded outcome observations. These trials are rare, however, because the majority of case reports in dermatology are published as consecutive cases of patients who have failed standard treatment. Usually, the treatment is compassionate and thus not usually administered according to a standard protocol.

The purpose of this chapter is to delineate the characteristics of high-quality case series, always keeping in mind that Phase III, randomized controlled clinical trials may never come. Whereas there is little literature, there is some on how to improve case reporting and case series: papers by Moses [5] and Abel [8] and

most comprehensively M. Jenicek's book *Clinical Case Reporting in Evidence-Based Medicine* [9]. The recommendations offered in this chapter rely heavily on this literature, which in essence uses the experience gained with cohort studies to improve case reports.

## Diagnosis

The authors of any case report or case series must explicitly state the diagnostic criteria used to establish the diagnosis of each patient reported so that others wishing to replicate the study may do so with similar patients. The diagnostic criteria may include histological confirmation, which should also be described in detail. Appropriate testing to exclude other entities in the differential diagnosis should be performed and reported.

## Inclusion and exclusion criteria

At the core of any description of case series is the delineation of exclusion and inclusion criteria. These criteria are often important to understand the clinical reasoning of the authors. They help the readers to apply the findings of the series to their patients and to define the external validity and generalizability of the findings, as they delineate the population to whom the observations are applicable. Inclusion and exclusion criteria are often used to increase the power of clinical trials by restricting studies to populations of patients who are most likely to respond based on their age, stage of the disease, or lack of concomitant diseases. While these selection criteria are likely to improve the outcome of any treatment, they introduce selection bias and seriously reduce the external validity of the study.

Detailing exclusion criteria can help to assure clinical safety, in that they describe who should not get the treatment in question. For example, patients with renal failure, children, or pregnant women may need to be excluded. The treatments that need to have failed before the experimental treatment is tried should be specified. Implicit inclusion and exclusion criteria are even helpful and illustrative in case reports, where they help the reader to identify the patients that the authors think due to theoretical considerations or knowledge about the side-effect profile of the therapy are not suitable for this therapy.

## Informed consent

Case reports and series are often the result of compassionate use rather than preplanned clinical trials. For the latter, informed consent and institutional review board (IRB) approval are required. IRB approval is not mandatory for compassionate use, but informed consent needs to be sought from the patient for any novel treatment. IRB approval indicates that the series has been collected prospectively, which is likely to signal higher quality by potentially reducing the selection bias that is likely in retrospective trials. That informed consent was obtained should be documented. As in any treatment, the authors should note that they have explained the risks and benefits and particularly the experimental nature of the treatment to the patients and that they have consented.

## Consecutive cases

The greatest threat to the credibility of case series is uncontrolled selection bias. Therefore, all consenting, eligible patients at an institution or under the care of one physician should be included in the

**Table 12.1** Methodology of case series.

Diagnosis	Are the diagnostic criteria clearly identified, and met by the patients included in the series?
Inclusion and exclusion criteria	Are inclusion and exclusion criteria clearly stated?
Informed consent	Has the patient consent been documented? For prospective studies: is IRB approval documented?
Consecutive cases	Are all consecutive patients treated by one physician or at one institution included?
Natural course of the disease	Is there any reference to the natural course of the disease, or, if applicable, the course on standard treatment?
Dosages	Are the treatments' dosage, duration, and titration described adequately?
Outcome measures	Are the outcomes of the therapy well defined and clinically relevant?
Patient perception	Is there any documentation of the patient's perception of the outcome of treatment?
Safety	Do the authors explain the toxicology and safety issues associated with the treatment? Do they abstain from unfounded claims about safety?

series. Feinstein pointed out rather elegantly that even this approach has inherent limitations, since the patient introduces bias by choosing the investigator rather than vice versa [10]. In spite of this potential pitfall, reporting “selected cases” introduces significant bias and severely limits the validity of such case series. If eligible patients refused to be part of the study or for other reasons did not receive the treatment, it should be noted and the reader should learn about their outcome. If patients were lost to follow-up, it should be documented. The patients who cannot be followed may differ significantly from those who come back. The former may be better, worse, or unchanged compared with the patients reported. If a number of patients are not accounted for, the series becomes a series of “selected cases” [5].

### Natural course of the disease

The implicit comparison for case series is either the natural course of the disease or the course under established treatment. Quite often the authors go to great length to describe a litany of failed treatments in order to describe the treatment-resistant nature of their patients’ conditions which they then go on to cure. However, many, if not most, dermatological diseases have a waxing and waning natural course. The knowledge of what may happen to the patient without the intervention is essential for the reader. For example, many interventions have been shown to halt progression of toxic epidermal necrolysis. This disease-arresting effect was observed usually after several “ineffective” treatment attempts had been tried in the patient. However, in untreated patients the average duration of progression is less than 4 days, which makes the interpretation of treatment that is initiated at or after this point impossible [11].

### Dosages

Information on dosages is an essential part of any treatment regimen. This admonition applies not only to systemic and topical treatment, but also to laser or other surgery. The treatments’ dosage, duration, and titration should be described adequately. For systemic treatments, the amount (total or per kilogram), number of times per day, and duration are important. For topical treatments, the preparation, concentration, vehicle, number of times per day, and duration are important. For laser treatment, “dosage” refers not only to the adjustments and types of laser, but also to the number of sessions that are needed to achieve a certain result. The authors should ideally treat all patients with the same treatment regimen, which may well include a protocol or policy for dose escalation or reduction; for example, steroid tapering. The reader needs to understand what dosages patients received, and if there were any differences among patients, then why some received more or less treatments than others.

### Outcome measures

The outcomes of the therapy should be well defined and clinically relevant. Very often, authors claim clear-cut disappearance of the skin lesions, and this outcome is a well-defined endpoint. However, not all (and in most cases, very few) patients in case series are cured, and the demonstration of clinical improvement is much more challenging. Ideally, the patients are assessed with established outcome measures like the PASI for psoriasis, SCORAD for atopic dermatitis, or CLASI for cutaneous lupus erythematosus. All of these

instruments have inherent and well-recognized limitations, and are not part of normal clinical practice. While desirable, the baseline assessment may be missing for patients treated compassionately. Treating physicians may fear the documentation of these baseline characteristics would constitute clinical research when initially the focus of the treatment is only patient care. In addition, many dermatologic diseases cannot be measured with available scales or instruments and the definition and description of the outcome are challenging.

It is not uncommon for authors to make statements about the therapeutic effect based on percentage improvement. This approach has its pitfalls, particularly if the disease, like most, has more than one dimension (e.g., a combination of pruritus, erythema, and scaling). More often than not, the authors do not describe what constitutes a 50% improvement, and often the content of this improvement remains unclear. The assessment of skin surface involved area is notoriously difficult and inexact. Whereas reference to the surface area involved gives the impression of precision, the accuracy and intra- and inter-observer reliability of these measurements is very low [12].

### Patient perception

The patients’ perceptions of the outcome of treatment should be documented. The patients’ perceptions of treatment are especially important given the difficulties in measuring and reporting outcomes noted above. Many dermatological treatments are tedious and expensive; thus, it is of great importance for clinicians to report whether patients were content with their treatment, and if they were not, what they did not like. If patients discontinue treatment, the reasons should be documented if they are known to the investigators.

### Safety

Safety data derived from small case series are rarely helpful and may be misleading. The data may be misleading if the author implies that the observation that no adverse events were observed in a series is relevant. As a general rule, the estimate of frequency of events derived from case series is imprecise. This imprecision can be estimated even for series without adverse reaction. You can determine the upper 95% confidence interval of the frequency of adverse reactions by referring to available tables, or you can calculate a reasonable approximation of the rate by dividing 3 by the number of patients that were studied [13]. The results illustrate that the small numbers found in case series do not document safety very well. For example, if no adverse events occur in a case series of 10 patients ( $3/10 = 0.30$ ), an underlying adverse event rate of 30% cannot be excluded. No events in 100 ( $3/100 = 0.03$ ) can still mean 3% adverse events. Thus, case series add little to knowledge about safety because they are unlikely to detect rare events and frequently miss common ones.

Usually, large cohort studies, case-control studies, or post-surveillance studies are needed to describe the risks associated with any treatment with authority [14]. Thus, to claim safety based on the absence of adverse effects in series of small sample size is inappropriate. However, the reader should be informed about adverse events or the lack thereof. We think that for case series it is appropriate to give further guidance on expected side effects based on what is known from the literature and previous experience with the treatment.

**Table 12.2** Reasons to be skeptical about case reports and case series.

Lack of test to placebo or vehicle control or standard treatment	Better than placebo or vehicle or just the result of the natural history in a fluctuating condition? Would this treatment perform better than the standard treatment? Case reports and series cannot be used to compare treatments with placebo, vehicle, or standard.
Recruitment bias	Were the patients chosen only based on their likelihood to respond to the treatment?
Information bias	Were the observers not blinded and thus potentially more likely to report favorable outcomes? Third-party assessment may partially overcome this bias.
Survival bias	Were some patients not reported who were originally enrolled? Patients who failed treatment may never have come back, or may have died.
Publication bias	The tendency to publish only positive results. Are there negative case series for the treatment in question?
Confounding	Could there be a systematic influence, beyond the treatment, that may have influenced the outcome? Confounding is hard to assess and cannot be adjusted for in absence of a control group.
Chance	Could the results have occurred by chance? Hypothesis testing is not possible for case series, and thus it is not possible to assess whether the result may reflect chance. While the population response rate or the overall natural course of the disease is helpful, it may not reflect the particular selected cases. Ideally, the reporter would not publish two or three dramatic cures but use these successes as a starting point for further observations, which would not include these first ones.
Regression to the mean	Were the patients recruited during a particularly bad phase of a fluctuating disease which would in most cases improve over time? Such effects are well documented in placebo-controlled studies.
Lack of formalized quality control	Is there any external formalized quality control to exclude fraud or data manipulation? Is there any conflict of interest?
Retrospective collection	Was the study only a retrospective collection of cases? Did the authors make sure that all patients in the institution that fit the inclusion criteria were included?

## Conclusions

Case series are, for pure reason of quantity, important sources of information about dermatological therapies, which is rather unfortunate, but unlikely to change in the near future. Owing to the lack of control groups, they can demonstrate efficacy of treatment only under rare circumstances (e.g., when the effect is dramatic and no other effective therapy is available). Given their low level of evidence and the many reasons to be skeptical about their findings (Table 12.2), it is mandatory that they are very well reported. Owing to their widespread use in the literature, there have been multiple attempts to classify and rate their quality; the referenced source is the most comprehensive [15].

If well designed, executed and reported, case series can be important clinical evidence that allows us to learn about alternative treatments before and perhaps in the absence of controlled trials. A poorly reported case series is likely to be unconvincing at best and misleading at worst, and thus it is important to stress that controlled high-quality clinical trials should be conducted if feasible.

## Acknowledgments

We thank Professor Hywel Williams again for valuable suggestions and editorial comments.

# What makes a good prevalence survey?

Hywel C. Williams

Centre of Evidence-Based Dermatology, University of Nottingham, Nottingham, UK

## Introduction

In addition to providing an estimate of the burden of skin disease in a given community, prevalence surveys (also known as cross-sectional studies or just “surveys”) make it possible to estimate the potential demand for medical facilities and the economic impact of a disorder. Comparison of data from prevalence surveys conducted in different populations with varying dietary and lifestyle habits may allow tentative inferences to be drawn about the association between a certain disease and its possible triggering factors [1]. Sometimes, sequential surveys are used to provide some evidence of effectiveness of an intervention. Prevalence surveys thus offer a means of estimating the prevalence of disease, its impact, and possible associations with risk factors, including population-based interventions. It is important to draw inferences only from high-quality surveys. But how do you tell a good prevalence survey from a bad one? This chapter discusses criteria that can be used to assess the quality and relevance of cross-sectional studies, with an emphasis on estimation of disease prevalence.

## The importance of clear reporting

Prevalence surveys, like other study designs, are prone to poor reporting and to bias, which results in reduced quality. Reporting refers to the extent to which items that should be described in a prevalence study are included in the study report. Study quality, on the other hand, is a judgment of how well the study was designed and executed in terms of reduction of risk of bias. Making a distinction between poor reporting and poor study quality is important as four scenarios are possible: a poor study that is well or poorly reported, and a good study that is well or badly reported [2]. Only well-reported studies make it possible for the reader to come to a judgment whether the study was of good quality or otherwise. In other words, complete reporting is a prerequisite to enable risk of bias (quality) to be judged. Thankfully, clear guidance on the reporting of observational studies have been developed by the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) group [3]. Although many of the recommended reporting items in STROBE are common to cohort, case-control, and cross-sectional studies, a specific checklist of 25 items for cross-sectional studies has been developed (<http://www.strobe>

-statement.org/fileadmin/Strobe/uploads/checklists/STROBE\_checklist\_v4\_cross-sectional.pdf).

Quality of reporting of observational studies in dermatology has been mixed, as was illustrated for prevalence studies of psoriasis in the second edition of this textbook [4]. One systematic review of 138 observational studies in dermatology assessed by the European Dermato-Epidemiology Network found that some key areas, such as sample size calculations, missing data, losses to follow-up, statistical methods, and funding sources, were frequently unreported [5]. The findings were broadly similar for the main types of observational studies, including cross-sectional studies. The conclusion is a simple one: observational studies in dermatology must report the key items that are needed by readers. Thankfully, many dermatology journals now make it a requirement for all observational studies to adhere to the STROBE reporting checklist [6], although how well journal reports stick to such guidance is worthy of further research.

## Quality criteria

A comprehensive guideline for evaluating the *quality* of prevalence surveys was that published in 1998 by Loney *et al.* [7]. They proposed eight main quality criteria, of which we suggest that the seven shown in Box 13.1 are useful for determining the quality of a dermatological prevalence survey. Each item is discussed in more detail.

### Specification of the target population

Published prevalence surveys should give a definition of the target population, which is the population to whom the researchers wish to generalize their results. Information about the geographical area covered, as well as age and gender, should be included. Whether certain population subgroups are excluded (e.g., certain ethnic groups) should be mentioned.

### Employment of adequate sampling methods

In most cases, it is impossible to survey the whole population of interest. It is therefore necessary to draw a sample that is representative of the population of interest. The best sampling technique is random sampling, in which a group of people are selected at

**Box 13.1** Criteria to consider when assessing the quality of prevalence surveys in dermatology

**Seven criteria that should always be assessed:**

- Was the target population specified?
- Which sampling method was employed? Is the survey based on a random sample or a whole population?
- Was the sample size adequate?
- Was the response rate adequate?
- Was information given on nonresponders?
- Was a valid and repeatable disease definition given?
- Have reasonable efforts been made to reduce observer bias?

**Other factors worth looking for:**

- Were inclusion criteria specified?
- Was information on persons actually studied reported in detail?
- Were known and validated instruments used for measurement of the health outcome?
- Were the terms “incidence” and “prevalence” correctly applied?
- Were confidence intervals or standard errors presented for the estimates of prevalence?

Adapted from Loney *et al.* 1998 [7].

random for study from a larger group (population). Each person is chosen entirely by chance, thereby reducing the likelihood of a selection bias favoring one group of people over another.

Cluster sampling – that is, sampling clusters of people, such as a random sample of villages within a region – is acceptable provided that the methods are clearly described and that the precision of the final prevalence estimate incorporates the clustering effect. Convenience samples – for example, a street survey or interviewing lots of people at a public gathering – do not provide a representative sample of the base population.

### Adequate sample size

The larger the sample, the narrower will be the confidence interval around the prevalence estimate, making the results more precise [1]. As no observed sample value exactly equals the population value, the confidence interval is a necessary parameter that describes the range of plausible values for the population parameter. Often, a “95% confidence interval” is quoted. The figure of 95% reflects the strength of belief that the computed interval actually contains the unknown parameter value [8].

The sample size required to estimate the prevalence of a disease with a certain degree of precision can be calculated. For example, following a review of surveys concerning the prevalence of psoriasis presented in the last edition of this textbook [4], we calculated that if the prevalence of psoriasis is assumed to be 2%, a sample size of 753 would be needed in order to obtain an error rate of  $\pm 1\%$  at the 95% confidence level. So with this sample size, and a real psoriasis prevalence of 2%, the prevalence value resulting from a survey could vary between 1% and 3%. The accepted error rate could vary depending on the assumed absolute prevalence of a disease. If a disease has a prevalence of around 10%, an error rate of 2% could be acceptable, resulting in a prevalence estimate with 95% confidence intervals varying between 8% and 12%. As the prevalence of psoriasis is not assumed to be that high, though, an error rate higher than 1% could result in imprecise outcomes. In order to guarantee the defined confidence level and error rate, and therefore ensure a specified degree of precision, it is necessary to define the

actual final sample size by subtracting the nonresponders from the initially determined sample size.

### Adequate response rate

If only a proportion of the invited people participate in a survey, selection bias may occur, thus affecting the validity of the findings [9]. Individuals affected by a certain disease could either respond more often than healthy people or rather tend towards nonparticipation. For population surveys, a response rate of 66–75% has been recommended as generalizable in the literature [10].

### Information on nonresponders

It is necessary to obtain information about nonresponders in order to make sure that they do not systematically differ from survey responders in terms of factors such as sociodemographic characteristics or the presence of disease. Researchers should try to follow up individuals who do not consent to participate in a survey and ascertain their reasons for nonresponse.

### Valid and repeatable disease definition

An important quality criterion for prevalence surveys is the presence of a standardized definition of the disease under investigation. A good disease definition is valid and repeatable. The term “validity” refers to the sensitivity (discerning as many cases of disease as possible) and specificity (excluding as many noncases as possible) of the definition [11]. A disease definition’s validity has to be tested on an independent sample before it can be used on the study population.

Ideally, a repeatable disease definition leads to similar results between several observers or within replicate measurements taken by the same observer. Testing of this criterion is also necessary before adopting a disease definition.

In the field of dermatology, valid and repeatable disease definitions are rarely to be found in prevalence surveys. Not one of the 22 surveys of psoriasis prevalence assessed in the last edition of this book assessed contained a valid disease definition – a pattern that has continued in subsequent studies [12,13], reflecting a research need to develop valid and reliable diagnostic criteria for psoriasis in population surveys.

### Reduction of observer bias

Observer bias may occur when a prevalence survey is based on clinical examination or on interviews. If there are several observers, their assessment concerning the presence or absence of a disease or of its severity could vary considerably. Even if only one examiner is responsible for the whole survey, observer bias may occur – for example, if the examiner has a lower threshold for diagnosing borderline cases of psoriasis in comparison with others or if they have a personal interest in a certain outcome, such as a company with a new psoriasis product that wishes to show that psoriasis is a big problem.

Thus, an attempt to minimize observer bias is mandatory for every prevalence survey. This task may be accomplished by adequate training of the examiners and by teaching them to rate the presence or absence of a disorder in the same standardized way. A comparison of the results of all observers may also show whether there is any inter-observer variability. If there is only one observer, it should be made clear before the onset of the survey that they have no personal interest in a particular outcome. Other methods of reducing observer bias include the use of photographs, which can then be assessed by an independent panel.

## Additional criteria

Other factors that should be taken into account when a prevalence survey is planned include the following.

### Specification of inclusion criteria for the study population

To allow for comparability between different prevalence surveys, it is important to specify inclusion criteria. These should comprise information about the age range and, if appropriate, gender and ethnic group of the individuals to be studied.

### Information on studied individuals

In addition to specifying inclusion criteria to denote who is eligible for study, a good prevalence survey should give basic demographic information about the individuals actually studied. Given that non-response is common, data on the population that is actually studied might differ from the specified inclusion criteria. For example, if a survey of psoriasis sets out to include all adults between 20 and 80 years of age, but individuals older than 75 years do not participate, the age range of the actually persons studied runs from 20 to 75 years. Valuable information about the individuals studied comprises at least the age range, ethnic group, and sex distribution.

### Measurement with valid instruments

A good prevalence survey describes the examination methods which led to its results. Furthermore, the instruments employed should be valid, displaying a high sensitivity and specificity. If an agreed standard measurement of a disease exists, with tested validity and reliability, then it should be employed, otherwise any other instruments used should have been tested previously in relation to the standard instrument.

In prevalence surveys, one method of measurement is clinical examination of the study population, especially when dealing with surveys of visible dermatological diseases. If this examination is performed by one or more trained specialists, a valid measurement is often assumed, since specialists are often used as a reference standard where no objective tests are available, as in psoriasis. Other common methods are questionnaires and interviews. Ideally, the questionnaires employed should have been tested for validity before being used on the study population [14].

### Correct application of epidemiological terms

It cannot be assumed that published prevalence surveys always apply the correct epidemiological terms for their findings. Sometimes, the terms “prevalence” and “incidence” are misused, the one being applied when in fact the other has been determined. A careful evaluation of the results with regard to their correct epidemiological relevance is therefore necessary.

In our previous review of prevalence surveys of psoriasis, one out of 22 surveys applied the term “incidence” (number of new cases per unit time) to its findings [4], when in fact the prevalence (number of cases existing at one point in time) had been determined.

### Confidence intervals or standard errors

The results for the prevalence of a disease derived from a prevalence survey provide only an estimate of the true prevalence in the larger population. Confidence intervals provide a range that contains the true population prevalence estimate with a certain degree of assurance, thus indicating the level of confidence one can have in the estimates. The degree of assurance commonly used is 95%.

Confidence intervals are influenced by the sample size. The larger the sample, the narrower the confidence interval and the more precise the estimate [15]. By calculating and mentioning confidence intervals for their prevalence estimates, quality prevalence surveys indicate their precision.

The standard error as a measure of the amount of sampling variability is also influenced by the sampling size [15]. The standard error reflects how much the estimate for prevalence fluctuates from sample to sample. A small standard error shows that different samples do not greatly affect the estimate for prevalence derived from the survey.

Thus, both confidence intervals and standard error are important for describing the reliability of the outcome of prevalence surveys. One of them should be computed and always reported in the results of a prevalence survey.

## Other checklists and scales

Searching for quality assessment tools is not straightforward as, unlike the EQUATOR Network – the resource center for good reporting of health research studies (<http://www.equator-network.org/>) – we are unable to find any resource that specifically collates instruments that assess study quality. We have searched the EQUATOR website and PubMed using terms “risk of bias AND assessment AND tool AND (surveys OR cross sectional OR prevalence)” and variations on these terms in order to identify further developments in this field.

Sanderson *et al.* [16] undertook a systematic review of tools used to assess the quality and susceptibility to bias for observational studies in epidemiology in 2007 which included checklists and scales that were recommended for a variety of study designs, including cohort, case-control, and cross-sectional (prevalence) studies. Only half of the tools assessed provided details on how they were developed. Most tools included items that related to methods for selecting populations (92%), how the study variable were measured (86%), sources of bias that were specific to the study design (86%), how confounding was considered (78%), and appropriateness of statistics (78%). The weighting and distribution of domains across the various scales was quite variable. The systematic review identified 19 instruments that could be applied for cross-sectional studies, six of which had been designed exclusively for cross-sectional studies [17–22]. Two of these were simple checklists [17,18], one was a checklist with additional judgments included [19], and three were scales [20–22]. None of the scales considered conflict of interest, and no recommendations were made by the reviewers on which instrument is “best” for cross-sectional studies. The authors instead commented on the lack of empirical evidence on which factors should be included in order to assess quality of observational studies, and that any new instruments should use evidence-based principles in their development and reporting.

A subsequent broader systematic review by Shamliyan *et al.* [23] assessing the quality of observational studies that examine incidence or prevalence and risk factors for diseases identified 46 scales and 51 checklists, only five of which were created for prevalence studies [23]. They commented that most numerical scales along with their arbitrary weightings of items were meaningless. They also concluded that poor quality of reporting was not separated sufficiently from poor study quality, and that it was rare for such scales to distinguish between internal and external validity.

The quality methods guide developed by the US Agency for Healthcare Research for Comparative Effectiveness Reviews in

2012 indicate some design-specific criteria to look out for in cross-sectional studies that are sometimes used to assess benefits of interventions [24]. These included uniform application of inclusion/exclusion criteria to all groups, adequate control for confounding, performance, detection, attrition bias, and publication bias.

The systematic review by Shamliyan *et al.* prompted Hoy *et al.* [8] to develop one of the most promising scales by Leboeuf-Yde and Lauritsen [25] that had been used to assess the prevalence of back pain in Nordic countries. Using rigorous methods to enhance inter-observer agreement, they suggested a checklist of four items for assessing external validity and seven items for internal validity, as summarized in Box 13.2. Responses for each item are classified as either low risk of bias or high (which includes unclear). Hoy *et al.* tested inter-rater agreement for the 11 items and found excellent levels of agreement for the individual items of the tool and moderate agreement for the summary risk of bias assessment. Further practical details on how to use this tool are given in the appendix of the online version of this report at <http://www.sciencedirect.com/science/article/pii/S0895435612000790>. Interestingly, all of the items mentioned in the checklist we developed in Box 13.1 are mentioned in the Hoy *et al.* checklist with the exception of items 8–11 inclusive. The division into items that denote internal from external validity in the Hoy *et al.* checklist and the fact that good inter-observer agreement has been shown for most of its items may make it an attractive checklist for use in assessing the quality of future prevalence surveys.

## Conclusion

Cross-sectional prevalence surveys are useful for estimating disease burden and costs, and they are sometimes very straightforward to undertake. As in any other study, it is possible to do a good or bad quality prevalence survey, and the factors outlined in Box 13.1 or 13.2 should be heeded when designing and setting up a prevalence survey. A good study design and execution does not always mean

that those reporting the results have included the important features. Better reporting of the quality factors outlined in this chapter is therefore crucial in order to allow readers to decide whether the results of a prevalence survey are valid and relevant to their population.

**Box 13.2** Checklist of four external validity and seven internal validity items to look out for when evaluating the quality of a cross-sectional (prevalence) study that has shown good inter-observer agreement

### External validity

- 1 Was the study's target population a close representation of the national population in relation to relevant variables?
- 2 Was the sampling frame a true or close representation of the target population?
- 3 Was some form of random selection used to select the sample, OR was a census undertaken?
- 4 Was the likelihood of nonresponse bias minimal?

### Internal validity

- 5 Were data collected directly from the subjects (as opposed to a proxy)?
- 6 Was an acceptable case definition used in the study?
- 7 Was the study instrument that measured the parameter of interest shown to have validity and reliability?
- 8 Was the same mode of data collection used for all subjects?
- 9 Was the length of the shortest prevalence period for the parameter of interest appropriate?
- 10 Were the numerator(s) and denominator(s) for the parameter of interest appropriate?
- 11 Summary item on the overall risk of study bias.

# Critical appraisal of pharmacoeconomic studies

Rajini K. Murthy, Laura K. DeLong, and Suephy C. Chen

Department of Dermatology, Emory University School of Medicine, Atlanta, GA, USA

## Introduction

Dermatologists are increasingly interested in pharmacoeconomic studies, with the realization that funds for health care are limited. This chapter outlines the four fundamental types of pharmacoeconomic studies (Table 14.1), gives dermatological examples, and concludes with a discussion of the necessary items for such studies. Readers can then critically appraise these studies.

## Cost analysis

Cost analyses are the most fundamental pharmacoeconomic study; they deal solely in costs of therapeutic interventions. Researchers can derive costs from either micro- or macro-costing. Microcosting involves enumerating each component of a therapeutic strategy and then determining the cost of each component.

Langan *et al.* [1] determined the annual cost of providing narrow-band ultraviolet B (nbUVB) phototherapy for psoriasis from a hospital perspective. Using the microcosting approach, they enumerated operational costs, nursing costs, consultant time, secretarial time, physics support, and nonconsultant hospital doctor costs. The total annual amount was €53 555 from the hospital perspective and €325 from the individual patient perspective. They found that 70% of the total annual cost of nbUVB phototherapy was due to personnel staffing. The remaining 30% of the total cost could be attributed to overhead costs for the phototherapy department. Although the cost of nbUVB for psoriasis is significant, they concluded that it incurs less cost compared with hospitalization and inpatient treatment. This study was conducted in Ireland, thus reflecting the inpatient perspective; in the USA, psoriasis patients are rarely treated in the inpatient setting.

Bialy *et al.* [2] compared the cost of Mohs micrographic surgery and traditional surgical excision (TSE) performed by otolaryngologists for the treatment of facial and auricular nonmelanoma skin cancer (NMSC). They itemized costs of the surgery, pathologic analysis, reconstruction, facility fees, and follow-up visits. They concluded that Mohs is cost comparable to two sequential TSEs with permanent section in the office (\$937 vs \$944) and was statistically significantly less costly compared with facility-based TSE with frozen section (\$956 vs \$1399). In another study, Rogers Coldiron [3] also compared the costs of treatment of NMSC, specifically

basal cell carcinoma (BCC) on the central cheek and squamous cell carcinoma (SCC) on the forearm. They performed a cost analysis of the following treatment modalities: electrodesiccation and curettage (EDC), imiquimod immunotherapy, Mohs micrographic surgery, TSE with permanent section margin evaluation in an outpatient setting, surgical excision with frozen section in both an outpatient and inpatient setting, and radiation therapy. They found that EDC is the least expensive option for treating an NMSC (\$471 BCC cheek and \$392 SCC arm). Similar to the analysis by Bialy *et al.* [2], they found that other lower cost treatment options for NMSC include office-based procedures such as Mohs micrographic surgery or TSE, or imiquimod therapy.

Macrocosting determines the overall cost to care for a particular disease, usually with a population-based approach. Kirsner *et al.* [4] evaluated the cost of hospitalization for dermatology-specific and diagnosis-related groups (DRGs) using the Medicare Provider Analysis and Review 1990–1996 database, which contains information for all Medicare beneficiaries using hospital inpatient services. The authors used codes for various dermatologic conditions and found that, in 1996, Medicare reimbursement was US\$52 million for dermatology-specific DRGs and US\$840 million for dermatology-related DRGs, a combined total of US\$892 million.

Cost analyses are useful as sources of rigorous cost accounting and as the basis for other pharmacoeconomic studies. However, they do not account for outcomes and potential side effects. Without accounting for the outcomes, the value of the therapeutic intervention cannot be easily measured. A costly medication that does not work well and does not provide quality outcomes has very little value. On the other hand, a costly medication that routinely improves lives may have very high value.

## Cost-effectiveness analysis

Cost-effectiveness analyses (CEAs) are one form of pharmacoeconomic analyses that incorporate both costs and outcome. The results of CEAs are presented as a cost-effectiveness ratio (CE ratio), with costs in the numerator and health outcomes in the denominator. The ratio is a measure of value; the smaller the ratio, the fewer the resources required for a given unit of health outcome. Costs are determined in the same manner as for cost analyses, as discussed

**Table 14.1** Summary of the advantages and disadvantages of different types of pharmacoeconomic analyses.

Type of pharmacoeconomic analysis	Advantages	Disadvantages
Cost analysis	Sources of rigorous cost accounting  Basis of other pharmacoeconomic studies	Does not account for outcomes and side effects  Does not measure the value of the therapy
Cost-effectiveness analysis	Accounts for outcomes and side effects  Measures value of the therapy	Outcomes are not standardized across disease processes  Results are not weighted according to importance
Cost-utility analysis <sup>a</sup>	Accounts for outcomes and measures value of therapy  Results are standardized	Need to invoke some external criterion of value to interpret results
Cost-benefit analysis	Accounts for outcomes and measures value of therapy  Does not need external criterion of value to interpret results	Assigning monetary value to health may be offensive  May be difficult to measure benefits in monetary terms for expensive and complex therapies

<sup>a</sup>Often called cost-effectiveness analysis.

above. The health outcomes are generally measured by some biological unit, such as intra-ocular pressure for glaucoma interventions, or by life-years saved for cancer chemotherapy.

CEAs compare at least two therapies – usually a new therapy is compared with a currently available therapy. A CEA that compares two therapies is called an incremental CEA; the additional costs that one therapy would entail are compared with the additional benefits that it provides. This CEA is in contrast to an average CEA in which the therapy in question is not compared with anything. However, the average CEA approach does not provide useful information to the policymaker or the clinician unless the currently available therapy is to do nothing.

Bergstrom *et al.* [5] published a CEA comparing the foam form and cream and solution combination form of topical clobetasol propionate for the treatment of psoriasis. They used the psoriasis area and severity index (PASI) score to measure their outcome. The difference in cost per change of one PASI unit using foam vs. cream and solution (US\$21.60 vs \$16.42 per PASI unit, respectively) was \$4.18; this was not found to be statistically significant ( $P = 0.20$ ).

CEAs provide information about the value of the therapeutic intervention in question by accounting for the outcomes of the therapy. However, the outcome measure is not standardized and therefore cannot be used to make comparisons with other disease processes. For example, a reasonable outcome measure for a new therapy for seborrheic dermatitis may be dollars per clear scalp. However, this measure cannot be used to compare with the CE ratio of new therapies for disparate diseases such as onychomycosis, venous ulcers, or acne. Even if “clear skin” is used as the outcome measure, it cannot be used to make comparisons with nondermatological problems. Another problem with CEA is that the outcomes are not weighted according to their importance. For instance, assume that new therapies for scalp psoriasis, onychomycosis and venous ulcers were cost effective compared with their respective

current therapies. Policymakers may not be able to incorporate all the therapies into their formulary because of budgetary constraints. They would need to decide which is the most important outcome: clear scalp, smooth nails, or a healed ulcer. A better situation would be to have the outcomes standardized and weighted according to value so that policymakers could compare CEA results across disease processes.

### Cost-utility analysis

Cost-utility analyses (CUAs) provide outcomes that are standardized and weighted. CUAs give rise to a ratio similar to that of a CEA except that the outcomes are measured in quality-adjusted life-years (QALYs). Note that many health services researchers use the two terms CUA and CEA synonymously [6]. QALYs reflect both the additional quantity of life that a therapy extends and also the quality of that additional amount of life. The latter measurement is particularly important in dermatology, where therapeutic interventions rarely save lives but often improve quality of life. In the QALY approach, quality of life (QoL) is measured by a set of weights called utilities, one for each possible health state, that reflect the relative desirability of the health state. The reader is encouraged to consult other references for detailed explanations of utilities [6,7]. By incorporating QoL and by standardizing the outcome measure with QALYs, a dermatology CUA such as acne therapy can be compared with a mortality-impacting CUA such as breast cancer therapy. There are few published dermatological CUAs, but a recent paper providing dermatologic utilities will provide a strong foundation for future CUAs [8].

Freedberg *et al.* [9] published a CUA comparing a one-time screening strategy for melanoma with a no-screening strategy. They primarily used life-years saved as their outcome measure, but they also used an estimate of utilities to estimate a QALY outcome. They found the CE ratio for the screening program to be US\$29 170 per life-year saved and US\$30 360 per QALY. While the strategy of screening once in a lifetime may not mimic reality, the analysis was a good beginning for investigating the cost effectiveness of melanoma screening. Before interpreting the QALY result (US\$30 360 per QALY), readers should realize that the criterion for cost effectiveness, called the CE threshold, is arbitrary and open to debate. A cost-effective therapy is one that delivers more QALYs per dollar (or costs fewer dollars per QALY) compared with some benchmark. Researchers consider therapies less than US\$50 000 per QALY to be relatively cost effective, whereas those greater than US\$175 000 per QALY are not [10–12].

Losina *et al.* [13] published a CUA comparing four different screening strategies for melanoma: background screens every 5 years, one time, every 2 years, and annual screening. The screening populations were the general population, having one first-degree sibling with melanoma, and two first-degree relatives/siblings with melanoma who were defined as being at highest risk. Inputs to their model were from the literature. Outcome measures included years of life saved and QALYs. They found that the most cost-effective strategy was a one-time screening of the general population at the age of 50 (\$10 100/QALY gained) and screening every 2 years in siblings of patients with melanoma (\$35 500/QALY for first-degree relatives and \$14 700 for highest risk siblings). These CE ratios were consistent with CE ratios for the recommended screening of other types of malignancies, such as breast and colorectal cancer.

With the advent and rising popularity of teledermatology, Parsi *et al.* [14] published a CEA comparing conventional in-office care

with a patient-centered online model for follow-up treatment of patients with psoriasis from the societal perspective. They did not find a statistically significant difference in mean change in QoL outcome, measured by dermatology life quality index (DLQI) scores, between the two groups. The DLQI score was converted to the EQ-5D (European Quality of Life Instrument-5 Dimensions) utility score using a formula. There was also no statistically significant difference in mean improvement in quality-adjusted life expectancy between the groups. However, the cost of follow-up psoriasis care through the online model was 1.7 times less than the cost of in-person visits. The paper reported both average and incremental CE ratios; the incremental CE ratio was \$16318 per QALY saved by the in-office group over the online group. This study concluded that costs were saved with online-care follow-up models while maintaining standard effectiveness of care similar to an in-office visit; however, their conclusions seemed based upon the average CE ratios rather than their incremental CE ratio.

Blank *et al.* [15] compared oral alitretinoin with supportive care plus emollients for the treatment of severe chronic hand eczema (CHE) nonresponsive to standard therapy (topical corticosteroids). Health states represented were clear/almost clear, mild/moderate, and severe nonresponders. Inputs were derived from two clinical trials. Direct costs were derived from market prices for drugs and insurance data for indirect costs. Clinical effectiveness was reported in QALYs extrapolated from data from severe psoriasis. They assumed that CHE patients had the same QoL impact as psoriasis patients and utilized the DLQI score reflecting the psoriasis severity. The DLQI score was then converted into EQ-5D utility weights using the same mapping formula in the above study. They concluded that treatment with alitretinoin resulted in a direct cost of €2212 and an average gain of 0.230 QALYs. Incremental CE ratio of using oral alitretinoin was determined to be €14816/QALY gained.

Of note, the EQ-5D measures health status very generally. Respondents describe the burden of their condition (no, moderate, and severe problems) in reference to five dimensions: mobility, self-care, usual activities, pain/discomfort, and anxiety/depression [16]. Preliminary data are conflicted as to whether the EQ-5D adequately estimates utilities [17]. While the DLQI is a validated instrument measuring disability and may convert well to the EQ-5D score, it remains to be seen whether the EQ-5D can estimate utilities well enough for CEA [16].

## Cost-benefit analysis

Cost-benefit analyses (CBAs) differ from CEAs and CUAs in that the results are reported as differences between the costs and health benefits of the therapeutic program. The health benefits are represented in monetary terms, usually by asking subjects how much they would be willing to pay for the therapy. The interpretation of a CBA is also different from that of a CEA or CUA. The CEA/CUA results give the value of a particular therapy relative to a standard therapy. However, in order to decide whether the new therapy is worth adapting at the expense of forgoing a different therapy, readers must invoke some external criterion of value, such as the CE threshold. The CBA, in contrast, allows the investigator to determine whether the therapy is worth the costs without an external criterion since all benefits in CBA are valued in monetary terms.

We [18] compared Goeckerman therapy with methotrexate for psoriasis using CBA in addition to the CUA described above. We queried a sample of “society” for the amount that they would be

willing to pay for each therapy if their insurance company did not provide for it. We found that there was no net benefit of Goeckerman over methotrexate. When we compared each therapy with a “do nothing” approach for different severity levels of psoriasis, only methotrexate produced net benefits for severe psoriasis.

Detractors of CBA cite a wariness of assigning monetary value to health because of moral and ethical issues [7]. However, proponents of the method point out that decision-makers who use the CEA/CUA implicitly place a monetary value on the health outcome since they choose some threshold below which they consider that the outcome is worth the cost [6]. Another disadvantage to the CBA method lies in the validity of the “willingness to pay” estimate of the value of the health benefits. Fortunately, many dermatological interventions are neither overly expensive nor complex, and thus it is reasonable to expect subjects to be able to conceptualize how much they would be willing to pay for a dermatological therapy.

## Guidelines for critical appraisal of pharmacoeconomic studies

Box 14.1 presents a checklist for readers of pharmacoeconomic analyses.

### Framework

To evaluate any pharmacoeconomic analysis, readers must bear in mind several points about the framework of the study. First, the study needs to be clear about the perspective of the analysis. Three main perspectives of a pharmacoeconomic analysis include the individual patient, the third-party payer, and society. The perspective dictates the cost used in the analysis (see below). The Panel on Cost-effectiveness in Health and Medicine has recommended including an analysis from the societal perspective [19]. Second, the target population to which the intervention is directed should be explicitly stated. Third, all pharmacoeconomic studies should be

#### Box 14.1 Checklist for readers of pharmacoeconomic analyses

##### Framework

incremental analyses, comparing at least two therapies unless no standard of care exists. Pure cost analyses can be an exception to this guideline since they can be used purely to account for cost. As noted in the Parsi *et al.* [14] study of teledermatology, different conclusions can be made if one uses average versus incremental analyses.

## Data and methods

Pharmacoeconomic studies should detail the pathway of the health intervention being analyzed, preferably with diagrams. In this way, readers can determine whether the proposed flow of health care is comparable to their own. If not, then the analysis may not be relevant. The study should be explicit in the types of outcomes used in the analysis, whether it is QALYs, life-years saved, or a disease-specific outcome. Awareness of outcome measures is especially important in analyses utilizing non-disease-specific health measures such as the EQ-5D. The methods for obtaining cost, effectiveness, and QoL measures should also be clear. If primary data are not available, the assumptions for using secondary data must be clearly stated, such as the alitretinoin study using psoriasis utilities as a proxy for CHE utilities, and a sensitivity analysis performed to ensure that the results are robust to these assumptions. A critique of the quality of the input data should also be explicit.

Several points about cost should be mentioned. The perspective of the study influences the costs used in the analysis. If an analysis is performed from the perspective of the individual patient, then only the costs relevant to the patient should be considered. These costs would include the copay that is involved with the physician visit and the drug, and the time off from work that is needed to see the doctor. Assuming that the drug is covered by insurance, the actual cost of the drug would not be factored since it is irrelevant from the perspective of the patient. On the other hand, third-party payers would be concerned about the cost of the drug as well as the cost of the physician, but not the copay or the time off from work. The analysis performed from the societal perspective would factor in costs that affect all members of society: the cost of the drug, the physician, and the time off from work, as well as any impact on family members. In the Blank *et al.* [15] study for CHE, the market prices of the drugs were used because the perspective was from the Swiss health system.

It is also useful to consider the categories of cost when evaluating a pharmacoeconomic analysis. Direct healthcare costs are the cost of the resources that directly provide the therapy. These include physicians, medications, laboratory monitoring, and radiography, for example. Indirect costs are those resources that relate to time and productivity. Indirect costs include the cost of the consumption of the time that the patient took from work, volunteer time, and family-leisure time. It can also include costs associated with the loss of or impaired ability to work secondary to illness.

The theoretically correct manner to estimate cost is by determining the opportunity cost. Opportunity costs consist of the value of forgone benefits; some other program must have been forsaken in order to pay for a particular therapeutic regimen. For instance, in a developing country, it might be necessary to sacrifice an education program in order to implement a vaccination program. However, sometimes one cannot assume perfect competition between two programs, so health-care prices may not approximate true opportunity costs. Instead, health economists use existing market prices to estimate costs. Readers should be wary of analyses that use charges to estimate costs, since charges rarely approximate the market prices of services. In general, analyses performed from the

societal perspective approximate the cost of physician and hospital services by using the Medicare reimbursement rate and estimate the cost of medication using the average wholesale price.

If the study analyzes the therapy over a long time course, then there needs to be an explanation of methods to account for inflation. Also, because, in general, people prefer to have money and benefits now rather than in the future, future costs and benefits in the analysis must be discounted. Experts recommend using a 3% discount rate [19].

## Results and discussion

Results should, at the minimum, be reported from the societal perspective. Results of sensitivity analysis should also be discussed. When assumptions have been made for the input data, those variables should be varied within reasonable clinical parameters. If the results change with variations in those variables, then readers should be wary of the robustness of the results. Finally, the relevance and limitations of the results to health policy issues need to be discussed.

# Comparative effectiveness research: what it is and how to assess its quality

**Junko Takeshita and Joel M. Gelfand**

Department of Dermatology, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, USA

## Why do comparative effectiveness research?

In spite of ongoing medical advances and cutting-edge biomedical research worldwide, much of medical decision-making by health-care providers and patients, especially in the field of dermatology, remains based on little scientific evidence. Randomized controlled trials (RCTs) have long been considered the gold standard of medical intervention studies. However, there is increasing recognition that the “average” effect that is measured in RCTs does not necessarily apply to all participants within a trial, nor is it reflective of how an intervention performs in the “real world” [1].

Whereas one of the great strengths of an RCT is its strong internal validity (i.e., similarity of characteristics in the control and intervention groups, resulting in high likelihood that the results of the study are “true”), RCTs generally have poor external validity (i.e., are not generalizable to a larger patient group). Characteristics of RCTs that contribute to poor generalizability include relatively short study periods (typically on the scale of weeks to months), specialized study populations with strict inclusion and exclusion criteria, comparison with placebo as opposed to a clinically relevant active comparator, and measurement of outcomes that may not be important to patients or relevant to clinical practice.

Results from RCTs, therefore, measure efficacy or how an intervention performs in an ideal, carefully controlled setting rather than the real-world clinical setting. The potential effects of strict inclusion and exclusion criteria of RCTs are exemplified by a study of a Spanish registry of psoriasis patients receiving biologic or oral systemic treatment which found 30% of patients to be ineligible for and unrepresented in RCTs [2]. This omission has important clinical consequences, as the patients who were ineligible for RCTs were found to be at higher risk of developing serious adverse effects compared with those who would have been eligible. This finding highlights the importance of determining not only which interventions are safer and perform the best, but also in which subpopulations of patients safety and performance are maximized.

In order for health care providers and patients to make informed medical decisions, they require guidance from studies that measure effectiveness (i.e., how an intervention performs in the clinical setting). Comparative effectiveness research (CER) is one method by which different medical interventions can be compared with one

another in order to determine the most effective methods of prevention, diagnosis, treatment, or monitoring for a particular medical condition.

CER is not a new concept, as comparative studies have been performed for many years. However, an interest in CER has been renewed due to the recognition of a need to address the aforementioned knowledge gaps in health care. In response, there have been international efforts to increase and incorporate CER into clinical practice. In the UK, the National Institute for Health and Clinical Excellence utilizes the synthesis of existing research and economic modeling to guide evidence-based medical decisions for the purposes of reducing variations in clinical practice, creating management guidelines, and setting quality standards. In Australia and Canada, CER efforts have been focused on pharmaceutical interventions and managed by the nationally run Pharmaceutical Benefits Advisory Committee and Common Drugs Review, respectively.

CER efforts in the USA have been slower to develop and were stimulated by the US Congress's establishment of the American Recovery and Reinvestment Act (ARRA) of 2009 which allocated \$1.1 billion to support CER practices. Under this law, the Institute of Medicine (IOM) was also charged with the task of establishing a priority list of CER topics with stakeholder (e.g., health-care professional, patient, policy maker) input to help focus national CER efforts. Of particular relevance to the field of dermatology, psoriasis, chronic lower extremity wounds, and acne are included among the top 100 identified priority topics for CER [3]. To further promote and fund research to guide medical decision-making, the Patient-Centered Outcomes Research Institute (PCORI) was created by the 2010 Patient Protection and Affordable Care Act. PCORI also includes an independent, federally appointed methodology committee whose purpose is to develop methodologic standards for patient-centered outcomes research ([www.pcori.org](http://www.pcori.org)) [4].

## What is comparative effectiveness research?

The IOM National Priorities Committee defines CER as follows:

Comparative effectiveness research is the generation and synthesis of evidence that compares the benefits and harms of alternative methods

to prevent, diagnose, treat, and monitor a clinical condition or to improve the delivery of care. The purpose of CER is to assist consumers, clinicians, purchasers, and policy makers to make informed decisions that will improve health care at both the individual and population levels [3].

Several other definitions of CER exist, all of which encompass the basic characteristics of CER and have been summarized by the IOM [3]. An essential defining concept of CER that differentiates it from other studies, namely RCTs, is that of effectiveness as opposed to efficacy. The differences between efficacy and effectiveness research are described in Table 15.1.

## Methods in comparative effectiveness research

CER, as it has been recently defined, remains a relatively new field, and CER-specific research methods are still in development. Commonly used methods are based on classic study designs and include those listed in Box 15.1.

Though the randomized effectiveness trial (i.e., “pragmatic” RCT) is the method of choice for studying the effectiveness of an intervention, as it would perform in the real world, the associated challenges remain, such as high costs, long study duration, and need for large study populations. Examples of pragmatic RCTs in dermatology include a Dutch study of home versus outpatient ultraviolet B phototherapy for psoriasis (PLUTO) [5] and a UK study of prophylactic antibiotics for prevention of cellulitis (PATCH II) [6]. The PLUTO study is a noninferiority trial that was designed to determine whether or not home phototherapy is worse than

outpatient phototherapy. This study is notable for its broad inclusion criteria and lack of fixed phototherapy protocol which also allowed for initiation of other medications as clinically necessary – both key characteristics of a pragmatic trial as discussed in detail later in the chapter. The PLUTO study found home phototherapy to be equally as effective and safe as outpatient phototherapy, and home phototherapy was associated with greater patient satisfaction. The PATCH II study similarly exemplified characteristics of a pragmatic trial but also experienced slow patient recruitment and a diminished sample size, demonstrating the logistical challenges of conducting RCTs.

Considering the challenges of RCTs, nonexperimental/observational studies remain an important tool for CER and are estimated to represent approximately 80% of current CER efforts, at least in the USA [7]. Observational studies provide the advantages of being less costly and time intensive (particularly if retrospective in nature), being more reflective of the real-world clinical setting, and providing a resource for information about treatments, such as adherence, use of concomitant therapies, and effects of treatment selection, among others. For example, in a cross-sectional study of the effectiveness of commonly used therapies for moderate-to-severe plaque psoriasis using data from the Dermatology Clinical Effectiveness Network ([www.dermcern.org](http://www.dermcern.org)), comparisons of adalimumab, etanercept, ustekinumab, and phototherapy with methotrexate suggested that the effectiveness of psoriasis therapies in clinical practice is not as high as what is reported in clinical trials [8]. However, the cross-sectional nature of the study rendered it susceptible to potential bias due to clinical drift. Clinical drift may result in overestimation of the effectiveness of therapies, as only patients with good responses will continue their particular therapies.

The potential for introduction of such biases (i.e., selection and information bias), which limit internal validity, is just one example of why observational studies tend to be the subject of criticism. Other reasons for criticism include the heterogeneous nature of observational studies and the analytic challenges created by use of a heterogeneous study population. To address these concerns, new epidemiologic methodologies, such as propensity scores and instrumental variables, which will be described later, have been and continue to be developed to strengthen the quality of observational studies for CER [4].

## Assessing the quality of comparative effectiveness research

A thorough discussion of quality assessment for all possible study methods available for CER is beyond the scope of this chapter. As pragmatic RCTs are the gold standard for effectiveness research and observational studies are the most commonly utilized for CER, our discussion will be limited to these two study methods and will also focus on those topics that are especially relevant to CER.

### What makes a good randomized clinical effectiveness trial?

RCTs can be broadly categorized as efficacy or effectiveness trials, sometimes also referred to as explanatory or pragmatic trials, respectively [9]. Explanatory trials are designed to determine the effects of an intervention under ideal circumstances and are most relevant to answering a specific research question about the benefit of a medical intervention. Pragmatic trials, on the other hand, are designed to determine the effects of an intervention under the

**Table 15.1** Differences between efficacy and effectiveness research.

### Box 15.1 Study designs for comparative effectiveness research

- 1 Experimental studies** (e.g., RCT). Experimental studies involve an active intervention to test a hypothesis. Of particular focus in CER is the design of RCTs that are more reflective of the real-world clinical practice, sometimes referred to as “pragmatic” RCTs. This includes head-to-head trials that compare more than one active intervention and use broadly representative study populations with less restrictive inclusion and exclusion criteria to maximize external validity.
- 2 Nonexperimental or observational studies** (e.g., cohort, case-control, cross-sectional). Observational studies do not involve an active intervention but rather rely on simple observation of events that occur in regular clinical practice in either a prospective or retrospective manner.
- 3 Research synthesis** (e.g., systematic review, meta-analysis). Research synthesis involves a summary of multiple existing studies to address a specific common question.

conditions in which it will be applied in the clinical setting and are, thus, the design of choice for CER [10]. In addition to the basic quality assessments of an experimental RCT, which are discussed in Chapter 9, there are several other domains that have been previously identified to be important to assess in a pragmatic trial, as summarized in Box 15.2 [11,12].

In an optimal setting, a pragmatic trial adheres to all of the characteristics listed in Box 15.2. In reality, however, few trials can be defined as purely explanatory or pragmatic and instead display a mix of characteristics. As such, tools have been developed to help classify trials as explanatory or pragmatic, including the tool by Gartlehner *et al.* [12] and the Pragmatic–Explanatory Continuum Indicator Summary tool by Thorpe *et al.* [11]. Additionally, guidelines for quality reporting of pragmatic trials have been developed as an extension of the Consolidated Standards of Reported Trials statement for RCTs [13].

### What makes a good comparative effectiveness research observational study?

Observational studies are generally considered inferior to experimental studies because of their poor internal validity due to lack of randomization which leaves them susceptible to bias (systematic error) and confounding (“a mixing of effects”). However, observational studies can be powerful tools for CER when utilized properly and with recognition of their limitations. Systematic error (i.e., selection and information bias) and confounding in observational studies may be addressed by a number of methodologic designs (such as exclusion, matching, restriction of study subjects) or by statistical analyses (such as restriction, stratification, mathematical modeling). The quality of observational studies depends on use of these strategies to ensure the study results are not meaningfully influenced by systematic error and confounding.

#### Box 15.2 Characteristic domains of a pragmatic trial

- 1 *Participant eligibility criteria:* Eligibility criteria are generally less strict than those of an explanatory RCT, and all participants who have the condition of interest are enrolled.
- 2 *Experimental intervention flexibility:* The experimental intervention is applied under flexible conditions to reflect clinical practice.
- 3 *Comparison intervention:* The comparison intervention is represented by “usual practice” or the best available alternative method that may include the option of “watchful waiting.”
- 4 *Experimental and comparison intervention practitioner expertise:* The experimental and comparison interventions are applied by a variety of practitioners under various clinical settings.
- 5 *Follow-up intensity:* There are no formal follow-up visits except for those required for usual clinical care. The outcome of interest is identified by administrative database search.
- 6 *Primary trial outcome:* The primary outcome is an objectively measured, clinically meaningful outcome to the study participants that does not require special testing or training.
- 7 *Participant compliance with the “prescribed” intervention:* There is no active measurement of compliance. No special strategies to maintain or improve compliance are used.
- 8 *Practitioner adherence to study protocol:* There is no active measurement of adherence. No special strategies to maintain or improve adherence are used.
- 9 *Analysis of primary outcome:* The analysis includes all patients regardless of compliance, eligibility, and other factors in a manner that is analogous to the “intention-to-treat” analysis.

Several tools have been developed to measure the quality of observational studies [14]. Unfortunately, no gold standard for quality measurement exists, and none of the existing tools have been fully validated. As a result, there is little agreement upon which tool, if any, should be used to assess observational study quality. There are, however, agreed-upon guidelines for the reporting of observational studies. These guidelines are discussed in the Strengthening the Reporting of Observational Studies in Epidemiology statement, which includes a checklist of items that should be addressed in all observational studies [15].

### Specification of study design

The study research plan should be detailed in the methods section with clear definitions of study purpose, hypothesis, study population and individual patient characteristics to be collected, intervention and comparators, outcomes, and benefits and risks to be measured.

#### Study population

The study population should be generally representative of the setting in which the intervention is to be applied. An important design to be aware of and assess for is the “new user design,” also known as an inception cohort. The new user design only includes those subjects who have never previously received the intervention of interest. It is the study design of choice because the inclusion of prevalent users may introduce a “healthy user” effect that falsely overestimates the effectiveness or safety of an intervention [16]. The new user design most reliably captures the full effects of an intervention by avoiding selection bias that can be introduced by including prevalent users who may have already survived past a certain time risk window for the outcome of interest, thus leaving fewer remaining high-risk subjects (a process termed the depletion of susceptibles).

#### Study intervention and comparators

The experimental intervention should be compared with an intervention that is reflective of usual care in the real-world clinical setting and may include the option of “watchful waiting” if clinically appropriate. Use of multiple comparators is preferable over a single comparator. The interventions should generally be commonly used and preferred interventions of medical providers or patients.

#### Study outcomes (effectiveness, benefits, risks)

The outcome should be relevant to stakeholders and provide evidence that will assist with medical decision-making or resource allocation. Direct clinical outcomes (e.g., mortality) are preferred over intermediate or surrogate endpoints (e.g., serum biomarker). However, in situations where measurement of the direct clinical outcome is prohibited by time, relevance, or cost, surrogate endpoints may be considered when there is a previously established direct relationship between the surrogate endpoint of interest and direct clinical outcome. In dermatology, where measurement of a direct outcome such as survival is not always relevant, outcomes should be prioritized according to stakeholder input and preference in order to maintain clinical relevance.

### Study conduct, analysis, and reporting

#### Data collection

For observational studies, data may be collected primarily (i.e., collected specifically for the study) or secondarily (i.e., collected for other purposes). With primary data collection, care must be taken

in the study design so as not to affect the usual medical practices of the health care provider. With both primary and secondary data collection, a thorough understanding of the data source is required to avoid introduction of bias and false interpretation of results.

### Data analysis and interpretation

Since observational studies are nonrandomized, data analysis should include methods to account for different subject characteristics among the comparator groups that may be associated with the study outcome (i.e., confounding). Methods to control for measured confounding factors include stratification, restriction, and matching according to the confounder as well as statistical methods to adjust for confounding. Unfortunately, it is not possible to measure all potential confounding factors, and residual unmeasured confounding may also impact the results in a manner that can be difficult to predict. To understand the potential effects of unmeasured confounders on the outcome, sensitivity analyses can be performed to estimate the effects of individual unmeasured confounders at various prevalence levels on the outcome of interest [17]. Any observational study should include at least one of these methods to manage confounding variables. If confounding is not accounted for in the study design or analysis, final effect estimates are referred to as “unadjusted” measurements and are likely to represent false associations in either the positive or negative direction.

When assessing observational studies, there are two main types of biases of which to be aware: information bias and selection bias. A thorough discussion of bias in observational studies is beyond the scope of this chapter, and the reader may refer to other resources for more information [18–20].

Of particular relevance to CER is a special form of selection bias called confounding by indication or channeling bias. Channeling bias specifically refers to the differential allocation of an intervention according to a subject’s likelihood of developing the outcome of interest. As a hypothetical example, in an observational study of adverse hepatic effects from methotrexate treatment of psoriasis compared with other systemic treatments, channeling bias may be introduced by the fact that dermatologists are more likely to prescribe methotrexate to patients with low baseline risk of developing hepatic complications.

Channeling bias may be addressed by several aspects of study design or statistical analysis, including controlling for known prognostic factors for the development of the outcome of interest and methods similar to those used to adjust for confounding variables, including matching, stratification, and restriction. Two newer methods that have been developed to address channeling bias include the use of propensity scores and instrumental variables.

Propensity scores measure a subject’s likelihood to receive a particular intervention and may be used to match subjects who are similarly likely to receive the interventions being compared [21]. Instrumental variables are factors that affect the outcome through an association with the intervention but have no independent effect on the outcome. Advanced statistical methods can be used to adjust for instrumental variables [22]; however, such methods are complex, and identification of a true instrumental variable is not necessarily easy. As an example, in a study comparing the effect of exposure to cyclooxygenase-2 inhibitors versus nonsteroidal anti-inflammatory drugs on gastrointestinal complications, an instrumental variable is the physician’s prescribing preference for one drug over another [23].

It is essential that every study include a discussion of potential biases and how they may affect the reported results in order to

guide the interpretation of the study findings. Even the most well-conducted observational studies and observational studies that use complicated analytic methods cannot be free of all biases. However, when appropriate study design and statistical methods to minimize confounding and bias are used, observational studies and RCTs across a number of research topics have been found to exhibit very good correlation, with only 16% of studies indicating significantly different summary results [24].

### Guidelines for reporting of observational comparative effectiveness research

New methodologies are being developed to address the particular challenges of CER, and guidelines for performance and assessment of comparative effectiveness studies are continuing to evolve. For more detailed discussions of recommended research practices, the International Society for Pharmacoeconomics and Outcomes Research has published a series of good research practices of observational CER studies using secondary data sources [25–27]. Because CER is a relatively new research field, validated tools for quality assessment for observational CER studies do not yet exist. However, the Good Research for Comparative Effectiveness (GRACE) principles – an accepted hierarchy of evidence and key elements of good research practice for observational CER studies – with an accompanying checklist have been compiled by the GRACE Initiative, a group of international experts in the field of pharmacoepidemiology, and are supported by the International Society for Pharmacoepidemiology (<http://www.graceprinciples.org/>). The purpose of the GRACE principles is to aid in the assessment of observational comparative effectiveness studies and may be referred to for more detailed information.

## Introduction

Engaging a patient in a therapeutic process involves assessing one or more outcomes. On an everyday basis, physicians and patients use outcome assessment instinctively, in the same way that Molière's Mr Jourdain was speaking in prose without knowing it. Asking a patient how they are feeling after the first 3 months of their treatment is outcome assessment. Here, the outcome evaluation has the advantage of being very feasible, almost universal, and suitable for many diseases and many patients. More specific outcome measures are also used routinely, generally, in nonstandardized ways.

In contrast, when a treatment is evaluated in a clinical trial, trialists go into great detail about outcome selection and outcome measurement. Several different outcomes are used in a given trial in order to evaluate the multiple facets of disease change. And the procedure of outcome measurement is (or more realistically *should be*) precisely documented. In a controlled trial, it is crucial to isolate one of the outcomes as the *main outcome*. The main outcome has to be the most relevant outcome regarding the study's main objective. It is used to calculate the sample size, and the fate of the trial rests on the result of the statistical test performed on the main outcome.

In the following sections, we will discuss several aspects in the "life" of an outcome, from the "producer" to the final user. Our emphasis and examples will be on clinical outcomes, but almost all the commentaries may apply to other types of outcomes; for example, radiology-based, pathology-based, or biological outcomes. Moreover, most of the elements are discussed in the context of clinical research.

## What can we do with outcomes?

### Elaborate

Many outcomes are based on scores measured on scales. Psoriasis area and severity index (PASI) is a well-known scale used in psoriasis research, and also used in routine patient care. The score is based on a semi-quantitative assessment of erythema, thickness, and scaling in four body areas. Numerical expressions of these

semi-quantitative assessments are then mathematically combined with categories of surface assessment to yield a score from 0 to 72. Examples of other scales used in dermatology include scoring atopic dermatitis (SCORAD), six area six signs atopic dermatitis (SASSAD), score for toxic epidermal necrosis (SCORTEN), and vitiligo disease activity (VIDA). There are many others.

An important point is to make the distinction between a scale (yielding a score value) and an outcome. For example, whereas PASI is a scale yielding a score, the "percentage of patients whose final PASI score value is less than 75% of their baseline PASI score value," commonly abridged as "PASI75," is an outcome, based on the PASI score. Another PASI-based outcome would be the percentage of PASI score improvement from baseline.

In a research paper assessing the type of outcome and the quality of outcome reporting, we proposed a typology of outcome construction by addressing three questions, and we formed the acronym "VIP," in which V stands for variable, I for items, and P for time-points [1]. The V question is about the type of variable for the assessment of the outcome at the group level (quantitative or qualitative – usually binary). The I question distinguishes collections of several individualized items (e.g., erythema, scaling, thickness, for PASI) from a collection of a unique item (or a global evaluation). The P question refers to whether the outcome is based on a collection of information made at the final point or on both initial and final points. Table 16.1 presents the breaking down of some outcomes with the VIP questions and demonstrates how different outcomes can incorporate the same scale.

This framework is useful to construct most of the outcomes. The way the information is collected is discussed further in the "Assess (measure)" section.

### Evaluate

Because outcomes are based on some kind of measurement, one should ideally be able to describe the qualities of the measurement. A measurement should perform well regarding three main characteristics: reliability, validity, and sensitivity to change [2].

Reliability, also called precision, reproducibility, and consistency, deals with the following question: Does the measure give the same

**Table 16.1** Examples of different outcome constructions (“VIP questions”: V, variable; I, items; P, time-points; see text).

Disease	Primary outcome as stated	Variable		Item		Time-point		Comment
		Type of final variable (used in the statistical analysis for a patient in each randomized group)		Method of data collection: multi-items vs single item or global evaluation		Time-points of patient assessment		
		Type	Explanation	Type	Explanation	Type	Explanation	
Psoriasis [9]	Percentage of PASI reduction from baseline to 12 weeks	Quantitative	Percentage of PASI reduction from baseline to 12 weeks	Multi-items	PASI (erythema, scaling, thickness, surface)	Initial and final	PASI at baseline and at 12 weeks	In the same article, the secondary outcome was binary: the proportion of persons with 75% PASI reduction
Atopic dermatitis [8]	Response rate at day 21	Binary	Response was defined as at least 60% reduction in the mLEASI	Multi-items	mLEASI (erythema, infiltration, excoriation, and lichenification)	Initial and final	mLEASI at baseline and at 21 days	
Bullous pemphigoid [9]	Disease control at day 21	Binary	Disease control at day 21 was defined as the absence of new bullae for the last three consecutive days	Single item	Number of new bullae	Final only	Number of new bullae on the last 3 days	
Cetuximab-associated acne-like eruption [14]	Lesion count at completion of treatment	Quantitative	Number of lesions	Single item	Lesion count	Final only	At the end of the treatment	

mLEASI: modified local eczema and severity index.

value each time it is measured? Reliability is affected by random error. Depending on the research questions, the main source of variability is between patients or between physicians who have rated the patients. Therefore, reliability is assessed as the consistency of repeated measurements by a single observer on a sample of subjects (intraobserver reliability), and by different observers performing measurements on the same sample of subjects (interobserver reliability).

Accuracy deals with the following question: Is the measure truthful, and does it measure what is intended? Accuracy is affected by systematic errors. A systematic error could be the result of observer bias, subject bias, or instrument bias. The accuracy is best assessed by comparing the measure with a gold standard; that is, a reference considered to be accurate. For most dermatological diseases no concrete gold standard exists; therefore, to assess how well the measurement represents the phenomenon of interest the convergent validity could be used. Convergent validity is the degree to which a measure is similar to (converges on) other measures that it theoretically should also be similar to. Other components of validity, such as face validity, are used to assess validity of a new instrument.

Sensitivity to change deals with the following question: Does the measure discriminate between the situations of interest? To obtain insight into the sensitivity to change, the scoring system should be assessed at baseline and during follow-up. Furthermore, effect size should be calculated. Therefore, agreement (reliability) between two observers on progression or regression in individual patients (Tx – T0 data) should be assessed. The percentage of patients with any change from baseline and the percentage of patients with clinically relevant change should be provided. It is important to know what constitutes the minimum clinically important change. Because such a definition is rarely available, a first step is to determine the smallest detectable difference that can be measured. A useful tool is one that detects clinically relevant changes rather than small changes.

Besides reliability, validity, and sensitivity to change, feasibility is an important dimension to take into account. Acquiring information on these parameters is done by performing studies dedicated to their evaluation. Those studies should be conducted on an appropriate sample of diseased patients in order to avoid spectrum bias and to guarantee acceptable external validity.

A “validated” instrument is an instrument for which all these important characteristics have been evaluated. Properly validated instruments with satisfactory qualities are rare, even in fields where scores are widely used, such as atopic dermatitis and psoriasis [3–6].

## Select

Outcome selection is driven by the objective(s) of the study. Several outcomes are usually necessary to capture the complexity of disease change. Classifications may be useful in order to select several dimensions of disease evaluation. There is no widely accepted typology of outcomes. They may be classified from the most objective ones (e.g., death, laboratory value) to the most subjective ones (e.g., pain intensity). The importance of incorporating patient-reported outcomes in any clinical research is increasingly recognized [7].

Using several outcomes has one main drawback, however. Making multiple comparisons between groups, as is usually the case in clinical research, increases the risk of falsely concluding an association (alpha-risk). Therefore, a hierarchy between the several selected outcomes must be set in advance, by isolating a “main” or “primary” outcome. The other outcomes are qualified as secondary outcomes. The primary outcome, with some acceptable exceptions, should be unique. In clinical research, the main outcome is supposed to be the most relevant outcome regarding the main objective of the research. Two additional qualities are required: first, the main outcome – but also secondary ones – must be clearly defined with no ambiguity in its entire definition; second, the way to express it, should be meaningful and “speak” to the end-user of the results.

Some effort is needed to improve outcome measurement in dermatology clinical research. In a systematic review of randomized trials dedicated to inflammatory skin diseases, 32% of 122 published articles had severe defects in those basic requirements [1].

The practice of using several outcomes has another drawback. Since there are large numbers of scales and their integration into outcomes, it is not uncommon that two trials on the same disease do not have even one outcome in common even though they may intend to assess the same domains. Between-trials comparisons of results are hampered by this inconsistency, as is synthesis of study results in systematic reviews and meta-analyses. These issues could be addressed through the development of an agreed-upon standardized collection of outcomes, known as a “core outcome set,” which should be measured and reported in all trials for a specific clinical area. The Core Outcome Measures in Effectiveness Trials initiative provides researchers with methodological resources to pursue the path to consensus rigorously [8]. In dermatology, the Harmonising Outcome Measures for Eczema (HOME) initiative is underway to select a core outcome set for atopic dermatitis [9].

### Assess (measure)

Once the outcomes have been elaborated, precisely defined, evaluated (ideally), selected, and hierarchized, the conditions for collecting data must be defined. In the context of clinical research, all these conditions must be clearly stated in the protocol, leaving no room for personal interpretation. A useful guidance is to follow the simple systematic questions of who, what, when, where (why), and how. We have proposed gathering all the elements defining an outcome, including its “VIP” structure and the conditions for collecting information, under the mnemonics “Kipling’s six honest serving-men and the blind VIP” (Box 16.1) [1].

One condition, requiring specific attention, is blinding. Together with randomization, blinding can be considered the most important pillar in the methodological architecture of therapeutic research [10,11]. The “double-blind” design refers to the patient and the care-provider being unaware of the assigned treatment. The “triple-blind” expression usually refers to the blinding of the statistician during the analysis. However, double-blind designs cannot always be implemented for practical or ethical reasons. Even in these situations, it is often possible, when the assessor is not the patient, to implement conditions for a blinded assessment. It may necessitate the use of a third party; for example, a physician who is not involved in patient care. Blinded assessment of the outcome is key to lessen bias in trials [12].

### Analyze

Analyzing outcomes is usually straightforward, provided that outcomes have been unambiguously defined. The statistical methods to be used depend on the types of variables but are out of the scope of this chapter. In some instances, the comprehensive definition of the outcome may lead to choosing between several types of analysis. For example, a proportion of patients reaching complete remission can be analyzed at multiple time-points (analysis of censored data) or at a fixed final time. More generally, if an outcome is selected at multiples times during follow-up, the time for the main analysis should be stated in advance since multiplying statistical tests inflates alpha-risk.

### Report

Reporting of outcome results should be complete. A complete outcome result for a randomized trial should include the value of

#### Box 16.1 Checklist proposal for the (primary) outcome description

##### Kipling’s six honest serving-men and the blind VIP

##### 1 Kipling’s six honest serving men\*: why, what, when, where, who, and how?

*Why* was this outcome chosen as the *primary* outcome?

*What* was the supporting “material” (e.g., photographs, lab result, patient)?

*When* was the final evaluation made (including serial evaluation in censored data analysis)?

*Who* made the evaluation (e.g., the treating physician, one or more independent evaluator(s), the patient, an automatic device)? If several evaluators were required, was a harmonization process implemented? How were conflicted evaluations on the same material handled?

*Where* was the evaluation made (usually the setting of the trial)?

*How* was the evaluation made; that is, any process used for collecting the elementary items used for the outcome construction. If several items had to be combined, how was that done; that is, using what algebraic or logical rule?

##### 2 “Blind”

Any procedure for implementing blinding should be described. Any procedure to evaluate the quality of blinding should be presented. Non-blinding during evaluation of the outcome conveys a risk of biased assessment.

##### 3 The three “VIP” questions for outcome construction

The three “VIP” questions (“Variable,” “Items,” “time-Points”) may appear as technical ones, but any clear description of an outcome allows rapid and unambiguous answers to these questions:

(a) What type of variable is attributed to a patient? (Binary, quantitative, other?)

(b) What type of information is collected? Multiple items? Single item? Or a global evaluation?

(c) What time-points are used to define the final outcome? Is the initial state a component of the final evaluation (“Initial and final time-points” versus “final only time-point”-based outcome construction). “Direct assessment of change” is a special case based on the contemporary assessment of both initial and final state.

\* Refers to Rudyard Kipling’s poem “I keep six honest serving-men”, *The Elephant’s Child, Just So Stories* (1902).

Source: Nassar *et al.* 2012 [1]. Reproduced with permission from *Nature*.

the outcome in each group (summary value and dispersion) and the result of the statistical test that compares those two results. An isolated mention of the degree of significance is not sufficient since it does not give an idea of the magnitude of the absolute value in each group and their relative differences. In the method section, the reporting of the definition of the outcomes and of the conditions of their measurement should be precise enough to answer all of the questions from the checklist “Kipling’s six honest serving men and the blind VIP” (Box 16.1).

Outcome reporting bias has emerged as a pervasive source of bias. Outcome reporting bias consists in not reporting the result of the primary outcome or post-hoc change for the primary outcome. Changes occur after trial completion and are oriented by the knowledge of the more favorable results. Changes may relate to the definition, the selection (outcomes not reported), or the hierarchy (a secondary outcome becoming the primary one) of outcomes [13–16].

### Criticize and use

All the preceding steps are meant to be critically assessed, with the main question in mind being “Is this result relevant to my practice

and my patient(s)?". Of course, this question implies focusing on more than just the outcome and demands that one critically appraise the study's objective, potential sources of bias, and external validity. Regarding outcomes, the main question is usually about relevance in the outcome selection and construction and, finally, appraising the importance of the difference between groups from a clinical perspective.

## Outcomes in dermatology and future directions

The number of skin diseases is impressively high with a great variety in expression. Patients' complaints and diagnostic analysis mainly rests on visible lesions, translating in a majority of outcomes being based on clinical examination. Clinical outcomes are less objective than radiology-based or laboratory-based outcomes, and therefore easier to create and modify. This contributes to the large array of scales and scores being available. One important challenge for dermatologists is to organize (as is underway for eczema with the HOME initiative) the selection of core outcome sets, disease by disease [9]. Another challenge, not specific to dermatology, is to think about outcomes and trials designed to compare treatment strategies, in order to assess effectiveness and tolerance in the long run for chronic diseases, rather than comparisons of efficacy for individual drugs in the short term.

The technical progress in photography and the shift to digital photographs make storage and transfer of images easy. This technological advance makes it possible to reassess and verify observations using images and, thereby, increases the number of assessors. Some practical obstacles persist; for example, standardization may be difficult to implement. Technical progress may overcome these difficulties soon, and we may have to rethink the construction and assessment of dermatological clinical outcomes based on these new technical possibilities.

# Where does qualitative research fit into evidence-based dermatology?

Ray Jobling<sup>1</sup> and Luigi Naldi<sup>2</sup>

<sup>1</sup> St John's College, University of Cambridge, Cambridge, UK

<sup>2</sup> Centro Studi Gruppo Italiano Studi Epidemiologici in Dermatologia, Department of Dermatology, Ospedali Riuniti, Bergamo, Italy

## Definitions

Qualitative research aims to gather an in-depth understanding of human behavior and the reasons that govern it. Researchers who use qualitative methods aim to “study things in their natural setting, attempting to make sense of, or interpret, phenomena in terms of the meanings people bring to them” [1], and they use “a holistic perspective which preserves the complexities of human behavior” [2].

Qualitative methods investigate the *why* and *how* of decision-making. They provide an opportunity to look deeply into the human illness experience by focusing on meanings, concepts, characteristics, metaphors, and symbols provided in the patient's story. It is about sensitivity to the nuances of that narrative. What is it that those encountering skin symptoms believe is wrong with them? How initially do those experiencing skin symptoms deal with it all? What exactly indeed do they *do*, as a result of their illness and all that goes with it; that is, what form does their illness behavior take? Has the advent of the internet made a difference, and if so how? Questions like these are the ones addressed by qualitative research.

## Qualitative research and evidence-based medicine

“... he was moribund and screaming . . . I examined him. He had obvious gross bilateral cavitation and severe pleural rub. I thought the latter was the cause of the pain and screaming. I had no morphine. . . I felt desperate. I knew very little Russian then . . . I finally instinctively sat down on the bed and took him in my arms, and screaming stopped almost at once. He died peacefully in my arms a few hours later. It was not the pleurisy that caused the screaming but loneliness. It was a wonderful education about the care of the dying . . .”

This passionate account comes from Archie Cochrane, one of the founding personalities of evidence-based medicine [3]. There are at least two components to any medical encounter, the relational one and the technical one. These two components are acknowledged in the definition of evidence-based medicine itself which states “the

conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients.” The patient's values, characteristics and circumstances matter in these decisions.

In spite of such considerations, emphasis in evidence-based medicine is usually given mainly to the technical aspects. Traditionally, clinical research has been characterised by a reliance on quantitative methods directed towards the generation of “hard” numerical data relevant to clinical practice. There has been an emphasis on aiming for narrowness and closeness of focus, precision, control and replicability; the application of statistical analytical techniques; and efforts to generate causality statements and “explanation”. With the emergence in medicine (or re-emergence since Hippocrates) of a model bringing together the biological and the psychosocial, the contribution of a qualitative approach integrating with quantitative evidence, has been advocated [4]. Examples are drawn from a few areas.

## Measuring disease

Attempts at the development of instruments for measurement and scoring systems have become a key feature of modern medicine. One example has been the ubiquitous reliance in research into psoriasis on the psoriasis area and severity index (PASI). Critics have of course pointed to the fact that in this important instance numerical scores have simply been accorded to subjective judgments of *severity*, bringing an appearance of objectively reliable data which is at least questionable. Undoubtedly, merging attempts at formal assessment and measurement of current severity via PASI (or similar) and life impact via dermatology life quality index (DLQI) with individual case analysis and qualitative data relating to lifetime experience would enhance the value of research. The complexity of interconnected symptoms of varying, fluctuating severity, individual adjustment, public response and coping behavior, all located within their “natural” setting rather than the artificial circumstances of the clinic, need to be investigated. In particular, the vital importance of a long-term perspective cannot be overstated since the most common major skin disorders are

characterized by extended chronicity [5]. Patients themselves (perhaps especially older psoriasis patients and/or those with an extended course of illness) may surprise their doctors for example by refusing a new or more zealously assertive therapy, preferring less or even no treatment at all, setting their current circumstances including their symptoms in the context of their own long experience of the disease and its treatment [6]. Instruments like the DLQI rely upon a few limited questions concerning recall of very recent life events, within the last month at the longest. In-depth interviews and other qualitative methods and analysis have suggested, however, that what matters to patients and influences their own judgment of the severity of their condition can be dramatically different from those formally measured by PASI/DLQI [7,8]. Sadly, there is all too little research evidence, and scarcely any that deals satisfactorily with cross-national or cross-cultural differences.

### Behavioral effects of disease and treatment

Human beings subjectively attribute meanings to their experience, drawing more or less, for better or worse on the resources made available by the culture surrounding them, their place in society and the social groups to which they belong. They make sense of and interpret what is happening around them, and attune more acutely to those that appear to be directly important to them. Their circumstances can and do naturally change, demanding dynamic responses across the life cycle for example but also day to day in a less organized and structured fashion. People react and act accordingly. The experience of illness, not only the underlying organic disease and the psychosocial organization and requirements of it and its treatment inevitably affects behavior, and potentially chronic dermatological illness can have life-long impact. Treatment regimens which are founded on a basis of scientific enquiry and understanding and the subjective beliefs, perceptions and judgments of clinicians will have a crucial role [9–12]. Therapy organizes, at times perhaps determines the form and content of the patient's experience of the illness. Those affected must make sense of it, and all that is entailed in terms of psychological and social consequences within the wider context of their lives. It is a reflexive process in that the illness, treatment, and behavioral accommodation within unfolding social circumstances and contingencies, will all interact and feedback in a subtle fashion [9,10].

### Stigmatization and coping

Fundamental questions are being posed for those affected: "What is happening to me? What do these experiences, feelings and events mean? In particular what does it all mean for me and my life? What can I do? What should I do, when, how, with what guidance if any, from whom?" Thus, there is more to skin disease than mere disease of the skin. It goes beyond biological disorder and dysfunction [11,12]. There are psychological, social, cultural, and economic dimensions, and also political factors which shape decision-making by those who fund or provide professional services thereby affecting the character, shape and substance of dermatological care [13].

Diseases like acne, eczema, vitiligo, and perhaps distinctively and notably psoriasis, do not manifest themselves simply as organic disorders. They also have a historically longstanding place in the public consciousness, constituting significant *social representations*, which involve imagery, ideas, perceptions, beliefs, attitudes, explanations and judgments [14]. They are elaborate social constructs built up over generations, constantly elaborated, amplified and reinforced in public discourse and social interaction. Therapeutic modalities constitute an important element, and historically they

have been a cumbersome burden to patients [15–18]. The adverse implications for affected individuals and indeed for those who seek to offer them support can amount to serious handicap [19]. They should be neither ignored nor dismissed. Thus stigmatizing social representations and connotations are a central feature and crucially important component of psoriasis as an illness and as a cultural and social phenomenon. Explanations of the processes of stigmatization founded solely upon biological thinking, study and analysis are likely to be unconvincing, whereas the conceptual and interpretative tools of the social sciences offer considerably more promise.

### Preferences and treatment adherence

Public and patients alike can remain stubbornly resistant to professional perspectives and persuasion; and medicines-use-behavior, for example, can be deliberately based on the exercise of choices at odds with medical advice and directions, in disregard of efforts to modify and "correct" them. Limited adherence is common [20–22]. Such behaviors must be seen and understood within the frameworks of meaning and understanding which patients bring to their treatment, together with the social and economic contingencies bearing down upon their lives. However, many studies of "compliance"/adherence behavior and related short-term cognitive/behavioral interventions designed to secure strict conformity to the demands of therapeutic regimens currently favored by health professionals, abstract particular specific behaviors from their wider meaningful context within an illness career spanning decades.

### Communication skill and patient narratives

For patients, narratives may provide important ways of communicating their experiences, expectations, hopes, doubts, pain, frustrations, joys, and needs. The organization of patients' narratives into a database has been attempted as a means to describe the widest practicable range of individual experiences from the patients' perspective [23,24]. Personal narratives presented without attempts at more formal analysis, may offer both data and insights worthy of attention for the qualitative experiential evidence they provide. There is much to be learned, for example, from revealing reflections by major authors who have experienced psoriasis and its treatment, presenting them in fiction, autobiographical accounts or media interviews. From the USA, John Updike gave telling accounts of the stigmatizing potential of chronic psoriasis, the character and impact of psoralen and ultraviolet A (PUVA), and the distressing reality of the failure of treatment [25,26]. These, in effect, represent fine examples of *auto-ethnography* and offer valuable insights. The British playwright Dennis Potter likewise wrote and spoke about the impact of his severely disabling chronic psoriatic arthritis and the treatment he received for it, in not only emotionally moving terms but also with information, insight, and illuminative reflection that should inform research [27]. His *The Singing Detective* is also notable not only in its own right, but also for the wide response it provoked from the audience and the media, scrutiny of which generated data directly relevant to understanding the cultural representation of the disease, popular understanding and misunderstanding of it, and the elaboration of stigmatizing connotations [28–30].

### Health-care models and organization

There is good evidence that clinical decision-making in medicine, including dermatology, can be influenced, indeed be founded upon, considerations other than scientific evidence, which may include tradition, national and local custom and practice, individual prefer-

ence, the commercial interests of pharmaceutical companies, and economic or political constraints [18,31–33]. An integration of quantitative and qualitative research is obviously needed to inform the organization of health care, to identify gaps in the ways care is delivered, and to define health-care models [34]. Integration of quantitative and qualitative research is especially relevant when caring for patients with chronic diseases. In the so-called “chronic care model,” self-management integrates with the health system, capitalizing on interaction between an informed patient and a prepared proactive team [35].

To summarize, the *disease* at issue may appear to be the psoriasis or eczema of the medical textbooks, narrowly depicted and addressed in terms of the biological sciences. But revealed by the instruments of qualitative research, the *illness* involves much more. It is a complex social phenomenon. It is a construction embedded in long-established cultural representations providing a framework, a repertoire, to be drawn upon for values, beliefs, perceptions, attitudes, prejudices, preferences, and behavioral patterns relevant to the process of coming to terms with symptoms, therapy, and the social reception of both. It sits within an elaborate social organization of which the delivery of care is a component part. Research which takes the character and content of the world-view and behaviors of health-care professionals as most important, presumes them to be unproblematic, and focuses solely on the diseases of patients fails to pose important questions, obscures critical evidence, and inhibits understanding.

## Methods

Qualitative research methods are founded on the notion that behavior and events occasioned by the onset and course of disease can be understood only if they are seen in their context, holistically, grounded upon a detailed well-documented description [36,37]. Methods used may range from textual analysis of documentary sources and patient diaries, passive observation of patients’ behaviors in certain settings, participant observation where the researcher is both part of the clinical setting and is also simultaneously an observer, audio and video recordings, focus-group discussions, and “in-depth” interviews (Table 17.1). In-depth interviews may encourage patients to relate experiences about their illness, thereby constructing a personal illness narrative.

Quantitative research should begin with an idea (usually articulated as a hypothesis), which then, through measurement, generates data and, by deduction, allows a conclusion to be drawn. Qualitative research, by contrast, begins with an intention to explore a particular area, collects “data” (observations and interviews), and largely generates ideas and hypotheses from these through what is known as inductive reasoning. The strength of the quantitative approach lies in its reliability (repeatability) – that is, the same measurements should yield the same results time after time. The strength of qualitative research lies in its validity (closeness to the truth). By deploying an array of selected data collection methods, good qualitative

research should deliver penetrative insight, reaching the core of what is going on rather than just skimming the surface.

The validity of qualitative methods is greatly improved by using a combination of research strategies, a process known as triangulation, and by independent analysis of the data by more than one researcher. The so-called iterative approach, altering the research methods and the hypothesis as the study progresses (in the light of information gleaned along the way), used by qualitative researchers shows a commendable sensitivity to the richness and variability of the subject matter. Failure to recognize the legitimacy of this approach has, in the past, led critics to accuse qualitative researchers of continually moving their own goalposts. Though these criticisms are often misguided, it has been recommended that qualitative researchers must allow periods away from their fieldwork for reflection, planning, and consultation with colleagues.

## Critical appraisal and meta-analysis

There is no hierarchy of evidence among methodologies for qualitative studies. The units of analysis in qualitative papers are the findings, presented as themes, metaphors, or concepts as identified by the researchers. By its very nature, qualitative research is nonstandard [38], and it is debatable, therefore, whether an all-encompassing critical appraisal checklist could ever be developed. Even if such a checklist may not be as exhaustive or as universally applicable as the various guides for appraising quantitative research, it is certainly possible to set some ground rules (Table 17.2) [36].

The synthesis or “pooling” of the findings of qualitative research remains a controversial area. Some researchers contend that, because of the “subjective” and individual nature of human experience, the findings of qualitative research are unlikely to be generalizable, whereas others consider that the heterogeneity of ideological, or methodological, backgrounds of the different approaches in the area hampers combination. In spite of these negative views, some attempts to combine study results are acknowledged as crucial if the findings are to have impact in policy and practice of health care [34]. Unfortunately, there is no emerging consensus on appropriate guidance for the systematic review of qualitative evidence. The two dominant, opposing views focus on interpretation, as in meta-

**Table 17.1** Methods used in qualitative research.

- Ethnography, including auto-ethnography and case study
- Direct observation
- Participant observation
- Focus groups
- In-depth interviewing: (a) unstructured; (b) semi-structured
- Documentary analysis/content analysis

**Table 17.2** Critical appraisal of qualitative research studies.

- 1 Does the paper describe an important clinical problem addressed via a clearly formulated question?
- 2 Is a qualitative approach appropriate? Exploration, interpretation, deeper understanding versus quantitative estimations.
- 3 How were the setting and the subjects selected? Was there an “average” view of a patient population, or an in-depth understanding of the experience of particular individuals or groups?
- 4 What was the researcher’s perspective, and has this been taken into account? It is important to recognize that there is no way of abolishing, or fully controlling for, observer bias in qualitative research. It is important that they describe in detail where they are coming from so that the results can be interpreted accordingly.
- 5 What methods did the researcher use for collecting data – and are these described in enough detail?
- 6 What methods did the researcher use to analyze the data – and what quality control measures were implemented? Analysis of qualitative data can and should be done using explicit, systematic, and reproducible methods.
- 7 Are the results credible, and, if so, are they clinically important?
- 8 What conclusions were drawn, and are they justified by the results?
- 9 Are the findings of the study transferable to other clinical settings? One of the commonest criticisms of qualitative research is that the findings of any qualitative study pertain only to the limited setting in which they were obtained. In fact, this is not necessarily any truer of qualitative research than of quantitative research.

ethnography [39] versus integration/aggregation; for example, in the methods developed by the Joanna Briggs Institute [40]. The usefulness of meta-ethnography lies in its ability to generate theoretical understandings that may or may not be suitable for empirical testing. Meta-aggregation is the preferred approach for developing recommendations for action.

## Final remarks

Qualitative methods are designed to reveal and illuminate the subjective meanings people attribute to the experiences and events which impact significantly upon their lives. The findings generated by qualitative research should, for example, inform, enable, and enhance understanding of the natural realities of the experience of disease and its treatment, and the behaviors that both may elicit [41]. Qualitative enquiry can stand comfortably and usefully alongside quantitative research, perhaps suggesting and exploring questions which can then be addressed in ways delivering quantitative results; or coming from the opposite direction, quantified data may be the better understood if they provide a start-point basis for the *conversation* with respondents which is intrinsic to qualitative research.

Whereas to date, understandably, the focus of qualitative study in dermatology has been almost solely on patients in this regard (as it is of course in quantitative work), there is every reason for widening the investigative gaze in future studies to include scrutiny of the attitudes, beliefs, and decision-making built into the professional world of the medical practitioners they consult and who are so crucial to the determination of the *trajectory* of their illness – that is, its shape, length, and character [15,42–44].

# Applying the evidence back to the patient

Hywel C. Williams

Centre of Evidence-Based Dermatology, University of Nottingham, Nottingham, UK

## Introduction

Applying external evidence from published papers back to the patient is perhaps one of the most difficult and least discussed steps of evidence-based medicine (Figure 18.1) [1,2]. Having unearthed some relevant, high-quality and valid information from clinical trials in relation to a clinical question generated by a patient encounter, five questions now need to be asked in order to guide the application of such information to that patient [3]. They are listed in Box 18.1 and discussed in turn below.

**Figure 18.1** Clinical trial evidence is all very well, but what if the patient in front of you says, “I don’t want that treatment.” What then?

## How similar are the study participants to my patient?

### Trial participants are often different from clinic patients

Participants in clinical trials may be different from the patient who originally prompted you to ask an evidence-based question – in obvious biological ways such as age, sex, and clinical disease type [4]. In most circumstances, these differences do not prevent you

from making some useful generalizations from the literature. For example, you can generalize from a randomized controlled trial (RCT) of topical corticosteroids for atopic eczema in the absence of strict diagnostic criteria, provided that the description of that disease is consistent with atopic eczema – for example, with phrases such as “itchy red flexural eczema.”

Occasionally, the description of the clinical trial participants may render it difficult to extrapolate study results to the patient in front of you. For example, it may be unrealistic to generalize the results of an RCT dealing with high-dose ultraviolet A in the treatment of young women with an acute flare of atopic eczema to an older man with extensive chronic lichenified atopic eczema. In such circumstances, perhaps more weight should be given to one trial of chronic eczema in adult men than to several trials conducted in younger women.

Perhaps one of the most frequent problems encountered is that of having to generalize trials of adult therapy to children, in whom RCTs are rarely performed. Children are not simply miniature adults, especially when it comes to dosing of drugs, which is often best done by body mass index or surface area rather than weight. Yet children can suffer almost all of the “adult” skin diseases, and practitioners frequently have no choice but to use adult-based data as a guide.

Another difficulty is that treatments that appear promising when tested in enthusiastic and relatively healthy clinical trial volunteers often turn out to be less effective when applied to a wider group of patients with other comorbidities and levels of compliance. Such a divergence between study participants and real patients has been termed the difference between efficacy and effectiveness [5]. A regimen that involves applying creams three times a day may be attainable under the special conditions of a clinical trial, with continuous encouragement from the study assessors (and sometimes financial inducements). However, when it is tried by busy working individuals, it may simply be too much trouble. Such effects can often be explored by looking at the dropout rate for different interventions and reasons for such dropouts. Finding poor compliance rates due to an inconvenient treatment schedule should not deter the reader from using the evidence, but rather make one more aware of the factors that need to be taken into account when

**Box 18.1** Questions that need to be considered when generalizing from studies to a patient

**Are the patients in these trials sufficiently similar to mine?**

- Do they differ in certain biological characteristics, such as age and sex?
- Do they differ in terms of disease subtypes – for example, pustular versus plaque psoriasis?
- Are there social factors that may diminish compliance?
- Does the patient suffer from other comorbidities, such as renal disease?
- Does the patient have a similar baseline risk of benefit or adverse events as the trial participants?

**Do the outcomes make clinical sense to me?**

- If a composite scale of signs and symptoms has been used, do you know what it means?
- Has the scale been deliberately selected or modified to enhance the apparent treatment effect?
- Are the main outcomes measured at an appropriate time point – for example, months for a chronic skin disease, or days for an infectious one?
- Has the patient's views of treatment benefit been considered?

**Is the magnitude of benefit likely to be worthwhile for my patient?**

- In addition to seeing whether a treatment produces statistically significant gain over its comparator, is the magnitude of that gain clinically worthwhile?
- Does the patient consider the magnitude of gain adequate to justify the risk and expense?
- Have you translated the magnitude of benefit into the number needed to treat for that patient's baseline risk – do you still think it is worthwhile?

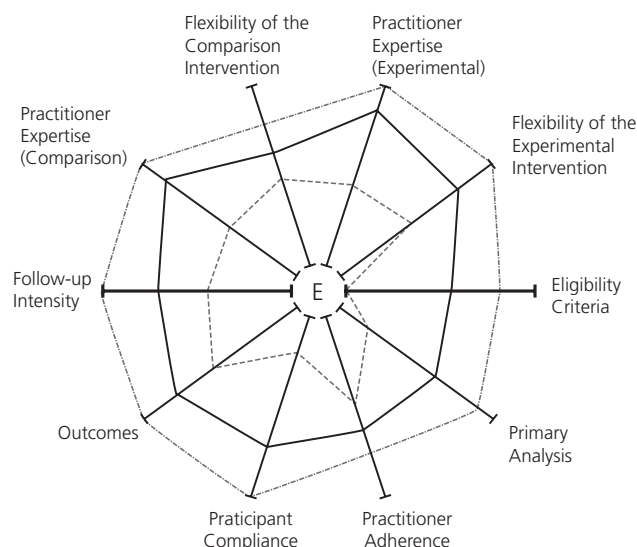

**What are the adverse effects?**

- Why did patients drop out of the studies?
- Have you considered rare side effects that might not show up in the trials?
- How will you communicate this risk of adverse events to your patient?
- How will you involve your patient in weighing up the pros and cons of the treatment choices?

**Does the treatment fit in with my patient's values and beliefs?**

- What is the patient's prior belief about the proposed intervention?
- Does the patient prefer a topical or systemic medication?
- Would the patient prefer no pharmacological treatment at all?
- What treatments has the patient had before?

describing the potential efficacy of a treatment to the patient. One type of trial design – namely, the pragmatic clinical trial – overcomes the “ideal patient” effect by recruiting as wide a mix of patients as possible and by capturing the effects of poor compliance in the final analysis [6]. Pragmatic clinical trials [7] are arguably the most informative type of clinical trial for generalizing to wider clinical populations, and examples of such trials may be found in dermatology [8,9]. The degree of pragmatism of a particular clinical trial can be estimated by means of a PRECIS (pragmatic–explanatory continuum indicator summary) wheel [10], which plots out the relative pragmatism for 10 different trial domains including eligibility criteria and follow-up intensity, as shown in Figure 18.2 for a trial of tetracyclines in bullous pemphigoid [11].

**Figure 18.2** PRECIS wheel showing the mean of the scores given by BLISTER trial management group members (solid line). Also presented are the most explanatory scores (inner line) and most pragmatic scores (outer line) given in each domain. Scores were plotted on the wheel using a simple picture editing program.

**Groups are different from individuals**

Even if the person in front of you is a woman with acute atopic eczema, the results of the trial may not translate into real clinical benefit to her, for several reasons. First, because the treatment effects reported in clinical trials – whether the outcome is a mean change in severity score or the proportion of people cleared – refer to *groups* of people. In a group of patients with a summary treatment effect such as a mean change in the scoring index of atopic dermatitis (SCORAD) of five points, there may be some individuals with score improvements of 10 or 15 points, some with changes of three or four points, some with no change, and possibly some whose disease has worsened. For example, closer inspection of the trial data on sildenafil (Viagra) for the treatment of erectile dysfunction [12] suggested that some men had all the fun! It follows that the patient sitting in front of you might benefit a lot or very little from the proposed treatment. Most trials in dermatology are underpowered to allow for subgroup analyses to determine which patients are most likely to respond well. Therefore, one sometimes has little way of knowing whether your patient will respond well or poorly apart from trying the treatment and seeing what happens. Similarly, telling your patient that “60% of patients on average clear with this treatment” may not be very helpful if the patient then asks, “Am I in that 60%, doctor?”

One way forward is to see whether treatment response varies according to different study subgroups. However, it is unusual for dermatology RCTs to be large enough to include such subgroup analysis, and care has to be taken to be aware of “data dredging” in studies with many subgroup analyses. Conducting a series of “*n* of 1” trials on a given patient may appear to be one way forward [13], but such an approach is only suitable for stable chronic diseases and for treatments that do not affect the response to subsequent treatments. Others have suggested sophisticated net benefit methods for estimating treatment effects for individual patients from clinical trial data [14], but such an approach is probably only

suitable for areas of medicine where huge amounts of trial data are available, which is not the case for dermatological diseases. Pharmacogenetic testing and biomarkers are other possible ways for predicting whether an individual will respond to a drug. For example, measurement of thiopurine methyltransferase levels predicts who will develop serious bone-marrow suppression from oral azathioprine [15]. Such stratified medicine using point-of-care testing is likely to play an increasing role in medical decision-making in future.

### Triumph of the aggregate

It is easy to misinterpret the application of aggregate data to individuals by equating group probabilities to individuals [16]. Thus, if a trial of excisional surgery for melanoma showed that 95% of participants (similar to your patient) were clear of the disease after 5 years, one cannot then tell the patient “You have a 95% chance of being clear at 5 years with this treatment,” since this 95% refers to the group and not the individual. The patient in front of you will either clear or not clear – the patient’s fate or response is already determined at that moment by that patient’s microdisease and other cofactors such as immunological status, much of which may be under genetic influence. However, it is correct to tell that patient that “95% of people similar to you are clear at 5 years.”

This inability to directly apply aggregate data directly to individuals is not unique to RCTs; it applies to most basic science [17]. Everyday “clinical experience” with a particular drug is, after all, a form of aggregation of data based on recollection of treatment responses amongst *groups* of previous patients. The same difficulties in predicting whether the next patient will respond to that drug, and by how much, exist more in anecdote-based clinical practice than in an evidence-based practice approach.

Thus, it is important to consider a number of factors when thinking about study participants and the individual patient [4]. There may be pathophysiological differences that could lead to a diminished treatment response. For example, people with atopic eczema may not respond well to reduction of house dust mites if they were not allergic to house dust mite in the first place. There may be important social and economic differences that may diminish treatment compliance, and hence response. For example, a single parent with four children and a full-time job may not have the time to diligently apply short-contact dithranol (anthralin) to their widespread plaque psoriasis every day. Comorbidities such as renal disease might also affect the treatment response, either directly by affecting drug metabolism and clearance or indirectly through drug interaction and compliance. Sometimes, the patient’s baseline extent of disease profoundly affects the effectiveness of the treatment being contemplated, in that those with little disease to begin with have little to gain. Patients with low potential to benefit from treatment also may still be at a high risk of adverse effects, thus resulting in a narrower risk/benefit ratio than those with severe disease [18].

### Do the outcomes make sense to me?

Even though you might have specified which outcomes are important in your structured evidence-based question – for example, “the proportion of patients cleared at 6 months” – very often the studies will contain a number of other short-term outcomes [19]. You then have to decide whether these outcomes provide useful clinical information. In most circumstances, there will be at least some information that makes some clinical sense to you.

### Take care in interpreting composite scales

Particular care should be taken in interpreting quantitative scales. Scales that combine several objective clinical signs and symptoms into an overall score are commonly used in dermatology RCTs. Despite their appearance of objectivity, most of them have rarely been tested for validity [20,21]. More importantly, such composite scales are often difficult to translate into clinical practice. What, for instance, does a difference of eight units ( $P < 0.05$ ) as the mean change in the psoriasis area and severity index (PASI) score from baseline between two treatments mean to you? Or when comparing methotrexate versus azathioprine for atopic dermatitis in atopic eczema, does a difference of 8.7 points using the SCORAD scale really mean that the two treatments can be considered equivalent [22]? Such scales are typically not linear (i.e., a patient with a PASI score of 30 is not “twice as bad” as a patient with a score of 15). A lot of psoriasis over the covered areas of the body does not mean more distress than a little bit of psoriasis on the backs of the hands and face.

### Sensitive scales amplify effects

Scales that are very sensitive to change amplify statistically significant changes that may be clinically unimportant. Take, for example, the trial of 2% minoxidil against placebo for androgenetic alopecia in women [23]. This study found a statistically significant increase in non-vellus target area hairs in the minoxidil-treated group in comparison with the vehicle-treated group after 32 weeks ( $P = 0.006$ ), although the “subjects discerned no difference.” The study, which was otherwise well conducted, should have concluded “something seems to be happening, but it is not clinically useful.” However, the authors’ conclusion was that “Two percent minoxidil appears to be effective in the treatment of female androgenetic alopecia.” Effective for whom?

### Too many scales and too many short-term studies

Given the profusion of scales used in dermatology (there are at least 21 named and at least 30 unnamed scales in atopic eczema alone) [21,24], it is quite easy to introduce bias by choosing a scale containing features that will enhance one’s own product in comparison with competing products. Introduction of a new scale is another potential source of bias, since they can increase the likelihood of showing a treatment benefit [25]. Lack of suitable long-term outcomes is another problem frequently encountered in dermatology clinical trials. For example, atopic eczema is a long-term condition for most sufferers, yet of the 272 RCTs summarized in a previous systematic review, most have been less than 6 weeks in duration [19]. Other factors, such as the frequency and duration of the remission, are key components in assessing the value of therapy. It is therefore important when reading a trial report to think of the time frame for outcomes as well as the type of outcome.

One significant advance in relation to outcome measures is the concept of development of core outcome sets. Core outcome sets simply refer to a small number (typically three or four) outcomes that should always be measured in clinical trials of a particular disease – usually a patient-reported outcome, an objective measure of clinical signs and a quality of life and adverse effect measure. The development of core outcome sets allows readers of published trials to make comparisons of trials that are conducted across the world as well as making it easier for them to be included in a meta-analysis within a systematic review. The Harmonizing Outcome Measures for Atopic Eczema (HOME) project is an example of an international group developing core outcome

domains and instruments for measuring those domains in atopic eczema/dermatitis [26], and links to similar initiatives in dermatology can be found from their website (<http://www.homeforeczema.org/>) or the COMET (Core Outcome Measures in Effectiveness Trials) initiative website (<http://www.comet-initiative.org/>).

### Look for outcomes that are clinically important

Although composite scales may be useful in the early development of a drug, in that they may show that something is happening, the key question within the framework of pursuing an evidence-based prescription is whether something *useful* is happening. Given the limitations of quantitative composite scales in dermatology, what should one look for in terms of outcomes that can best inform practice? In the absence of established core outcome sets, see what the patients who participated in the trials thought of their treatment, using simple measures such as the proportion of participants with a “good or excellent” response or simple categorical measures such as percentage cleared. Did the patients’ quality of life improve? Although such measures are subjective, reduction in distress is the precise treatment goal for many chronic skin diseases? Patient center outcomes help generalize the meaning of treatment responses across cultures, since some cultural groups may voice their complaints more or less than others.

Objective measures are, of course, also needed, especially when interventions are not blinded. Objective measures are also more useful in some diseases (for example, to assess the histological clearance of treatments for basal cell carcinoma). Again, the objective outcomes need to be simple enough for most physicians and their patients to understand (for example, the proportion of recurrences within 5 years, rather than hazard ratios for first recurrence).

## Magnitude of treatment effects

### How big?

Even if a trial yields a result that is clinically meaningful, it is important to ask, “Is the *size* of that benefit likely to be helpful for *my patient*?” Even when the study benefits are of large magnitude, they may still not be enough. Consider a patient with a facial port-wine stain who is treated with pulsed tunable dye laser, and who achieves a 70% reduction in the total surface area involved. We might be impressed by such a magnitude of gain, but if the patient is still unhappy because they feel that the stigma associated with the residual lesion is just as disabling, or that the odd pattern of circular pale holes left by the laser within the lesion draws even more attention to it, then this is a treatment failure.

Thus, it is crucial to consider not only whether a treatment is effective in a published report, but also *how* effective it is. Large studies tend to find small but possibly clinically irrelevant benefits, and large benefits reported in first reports tend to be reduced or contradicted in subsequent studies [27]. It follows that an important part of the discussion with the patient is to agree on what is possible or not possible in terms of realistic treatment objectives.

### Number needed to treat

Because many interventions in medicine are of only modest effect, their apparent benefit may not be that noticeable after one has tried the intervention on a few patients. One way to understand the magnitude of benefit in relation to baseline risk is to use the concept of “number needed to treat” (NNT) [28]. NNT refers to the number of patients that you would need to treat in order to see one addi-

tional success in the new treatment in comparison with another treatment. NNT is calculated simply as the reciprocal of the difference in success rates between the treatments being compared. Thus, a new treatment that results in clearing of psoriasis in 40% of patients, compared with 30% for the conventional treatment, translates into a risk difference of 10% (40% – 30%) and an NNT of 10 (1/0.10). In other words, one needs to treat 10 patients to clear one additional patient.

Patients’ and physicians’ views regarding the threshold for what might constitute a useful NNT may differ significantly. Thus, in a study of perspectives of physicians and patients on anticoagulation for atrial fibrillation, patients placed significantly more value on the avoidance of bleeding than did doctors [29]. Again, the message here is not to think of NNT as belonging exclusively to doctors – patients also need to be incorporated into the decision-making process in determining what is useful and important.

It is also important that the dermatologist and patient decide for themselves what might constitute a useful NNT, rather than accepting the conventions that have been derived from acute medicine. For example, it may be perfectly justifiable to treat 200 patients with low-dose aspirin in order to prevent one stroke. It would certainly not be justifiable to treat 200 patients with a new antibiotic to gain one extra short-term remission of acne. In a pressurized health service, the value of a new treatment for plaque psoriasis with an NNT of 20 might be questionable. Perhaps the opportunity costs associated with seeing and treating the extra 20 patients needed in order to achieve one extra response from the new treatment could be better spent discussing other treatment options with them, or assessing other new patients. Despite these caveats, the NNT is a more useful tool than relative risk or odds ratios for translating the evidence back to the patient. The concept of NNT may also be applied to adverse effects where it is known as the number needed to harm. A detailed review of NNT in dermatology may be found elsewhere [30].

## Adverse events

### Trials are not a useful source of rare but serious side effects

As highlighted in Chapter 10, adverse events are often overshadowed by an emphasis on the positive treatment benefits in clinical trials. Details of reasons for withdrawals are frequently missing from trial reports altogether, and failure to perform an intention-to-treat analysis may compound this omission, as dropouts may be related to lack of efficacy or to adverse events that are not obviously related to the trial medication [31]. Rare but important side effects such as minocycline pigmentation are unlikely to show up in small clinical trials and often emerge as subsequent case reports or during postmarketing surveillance. Simply stating that no serious liver problems occurred in 100 patients taking traditional Chinese herbs for atopic eczema is still compatible with an upper 95% confidence limit of 3% if a larger population were tested [32].

Particular efforts should therefore be made to scrutinize trials for a list of the frequency and severity of adverse events, as discussed in Chapter 10. As the events surrounding the thalidomide tragedy remind us, caution should be exercised when using new treatments that have not been tested on thousands of patients. Additional literature sources and postmarketing surveillance studies need to be scrutinized before one can reassure patients on side-effect issues with a reasonable degree of certainty.

## Limitations of aggregate data

Just as for assessing treatment benefits, aggregate data on side effects can be misleading. Thus, when comparing two types of corticosteroid, one may find that the mean decrease in skin thickness is similar in the two groups. However, if further scrutiny of the individual data shows that two children in one group developed skin thinning with noticeable visible striae, then that observation might influence your decision not to use such a treatment, despite the relative reassurance provided by the group means.

## Communicating risks

How to communicate risk presents its own problems, with different conclusions being reached by doctors and their patients, depending on how the information is presented in terms of relative or absolute risk [33]. Paling and others suggest that supplementing verbal data with numerical data is key [34,35]. Absolute numbers, rather than relative or percentage changes, should be used, and the same denominator should be used to compare with other risks in order to provide context. Risk should be communicated in straightforward numbers that are easily understood, such as 1 in 1000, and the figures should relate to a specific time period – for example, per year or lifetime. Visual aids, such as those depicting what can happen amongst a group of a thousand people undergoing an intervention (the Paling Palettes, <http://www.riskcomm.com/palettes.php>), can be especially helpful [34].

Even when the risks are understood, weighing up the pros and cons of an intervention is a highly variable affair. It depends on the type of information presented to the patient, and the manner in which the information is presented. Thus, a doctor who believes that a patient with psoriasis needs ciclosporin may play down the possibility of permanent kidney damage by their body language and by saying that they have treated hundreds of patients without any problem. However, for another patient who has requested the same treatment, but for whom the doctor considers ciclosporin inappropriate, he or she may use the very same potential adverse event as a “threat” to dissuade the patient.

## Decision-aid approaches to weighing up risks and benefits

Combining the values of treatment benefits versus risks for individual patients has been tackled using approaches such as decision analysis – a process in which the sequential choices faced by patients are made explicit [24,36]. Patients are then invited to place their own values on the various potential gains and losses. These decision-aid methods have been used extensively in areas such as amniocentesis for detecting fetal abnormalities, but less so in dermatology [25,37,38]. Simplifications of a decision-analysis approach, such as the likelihood of being helped or harmed, have been advocated by others [26,39].

## What are the patient’s values?

### Values and belief models

Even if the external evidence suggests a good treatment for your patient, they might have a number of reasons for choosing or not choosing that treatment. For example, a teenager who consults you with acne, whose friend developed hepatitis whilst taking oxytetracycline, might initially refuse that treatment option. If that drug is really the best choice, the dermatologist can explain how rare such an event is and reach a joint decision with the patient. Another

patient with acne might come demanding treatment with isotretinoin simply because their friend at school had similar treatment with excellent long-term results and tolerable side effects. Although such a declaration might influence the consultation, it does not automatically mean that the dermatologist will concede to such a request if they feel that the treatment is not in the patient’s best interest (for example, very mild disease or a history of several unplanned pregnancies). Application of the best external evidence requires a dialogue with the patient in order to explore their values and expectations.

Patients sometimes prefer to use something that they perceive to be more “natural” – for example, evening primrose oil rather than synthetic topical corticosteroids for atopic eczema. Sometimes patients prefer to forgo pharmacological treatment and instead undertake various measures to manipulate their environment. Others just prefer to take a few pills and forget about it. Some like creams, others like ointments. Some people do not wish to be involved in lengthy discussions of treatment options if indeed they believe that their doctor is the best person to help them choose a treatment option. For example, a person with a basal cell carcinoma may be happy to be recommended surgical excision rather than debate the 10 or so treatment options available to treat such lesions.

Issues of personal perception, belief models, locus of control, and personal experience should all contribute to the richness of a consultation with a patient. Although patients’ treatment choices may at times appear to be at odds with the external trial reports, patients are human beings who have their own sets of preferences and values, and these preferences need to be respected and understood [40].

## And if the treatment still does not work?

After agreeing on a treatment, a patient may return saying that the treatment does not work. After obvious issues have been explored, such as compliance and whether adverse events can be avoided (e.g., the presumed “allergic reaction” from topical benzoyl peroxide may be a predictable irritant reaction that could be circumvented by less frequent or vigorous application), other treatment options are often discussed. If several treatments fail in a particular patient, the patient may belong to a subset with refractory disease, making it even more difficult to generalize from clinical trials of people with more responsive forms of the disease. Dermatologists frequently face the problem of trying several drugs in succession. External trial evidence could be improved by better descriptions of study participants in terms of previous treatments, and by means of sequential RCTs that try different treatment approaches following failure of a treatment.

## Conclusions

Applying evidence back to the patient is often the most difficult and neglected step in the practice of evidence-based dermatology. The question of how best to relate universal evidence to the particular has always been a doctor’s dilemma. Clinical judgment is at the heart of this process [28,41], and requires consideration of several factors, including an appraisal of the magnitude and meaning of the treatment benefit and adverse events in relation to the patient’s values and preferences. Presenting the evidence back to the patient is a complex process requiring good communication skills and an appreciation of the limitations of the generalizability of trial data in terms of trial participants, relevance, and trade-off between benefits and harms.

### CHAPTER 19

## Acne vulgaris

Michael Romano and Robert P. Dellavalle

Department of Dermatology, University of Colorado Denver, Aurora, CO, USA

### Background

#### Definition

Acne vulgaris is a pervasive disease of the pilosebaceous follicles of the skin, which are located on the face, back, and chest. The disease has a range of clinical expression and can be classified according to the predominant lesion type:

- Noninflammatory or comedonal acne is primarily composed of open comedones (blackheads) and closed comedones (whiteheads), with little or no inflammatory involvement.
- Inflammatory acne is characterized by inflamed lesions (ILs: pustules, papules, and nodules) and can be further subdivided into papulopustular, nodular, and conglobate, depending on the predominant lesion type.
- Conglobate or nodulocystic acne is characterized by ILs that have progressed to form abscesses or granulomas [1]. Acne fulminans is a severe form of conglobate acne.

#### Incidence/prevalence

Estimates of overall prevalence vary considerably and depend on the study populations and epidemiological methodology used. The disease is defined by a continuum of severity (Figure 19.1), along which members of the adolescent population are placed; it is estimated that up to 30% of teenagers have acne of sufficient severity to warrant medical treatment [1]. An increasing number of women in their twenties develop late-onset acne, and surveys of adults over the age of 25 years have reported prevalence of 22% in males and 40% in females [2,3].

#### Etiology/risk factors

Acne results from pathological changes in the pilosebaceous duct (PSD). Thickening of the follicular stratum corneum (hypercornification) leads to blockage and accumulation of sebum, which is produced in large quantities in response to the androgen surges that accompany puberty. The resident skin commensal bacterium, *Propionibacterium acnes*, proliferates in the lipid-rich sebaceous follicles, causing accumulation of bacterial metabolites, sebum, and dead cellular material. Follicular occlusion blocks discharge, and an inflammatory response ensues. The extent and duration of the inflammation, and hence the severity of the acne, may be determined by individual variation in the immune response to *P. acnes*.

The onset of acne is associated with adrenarche, although androgen markers and mild comedonal acne have been detected in children under 10 years of age [4,5], particularly in girls who have an earlier onset of puberty [6]. Although the overall incidence is roughly equal in both sexes, with the peak rates occurring at 17 years of age [7], boys tend to have more severe disease [8]. There is no evidence that ethnic or racial differences influence the development of acne, although blacks have a higher incidence of disease [9]. Whilst genetic factors are also thought to influence susceptibility to acne [10,11], the mode of inheritance has not been determined.

#### Prognosis

Most cases of adolescent acne clear spontaneously over time. There are, however, two common forms of postadolescent acne: persistent acne commences in adolescence, but does not resolve and is generally resistant to antibiotic therapy, and late-onset acne is generally less severe, evolves more commonly in women after 25 years of age, and has been linked to abnormalities in plasma androgens [11,12].

The total burden of acne extends beyond financial costs; the impact on the individual can be devastating, as the disease occurs at an age when its effects are acutely felt. The cosmetic changes associated with acne have been linked to anxiety, depression, social isolation, and interpersonal difficulties [13].

#### Aims of treatment

Treatment aims to alleviate symptoms and accelerate healing of lesions in the short term, and in the longer term to limit disease activity, scarring, and the impact of the disease on quality of life.

Treatment options are commonly classified according to route of delivery and mode of action. The comparative data on various therapies are limited, and individual trials have obtained contradictory results, largely because of inadequate trial design and unfair comparisons in terms of dosage. Isotretinoin is the only acne treatment that can induce persistent remission. All other acne treatments are palliative, and whilst improvement of symptoms and control of disease progression is possible, prolonged therapy is needed.

#### Relevant outcomes

Disease severity is assessed by a visual assessment of the number of lesions and extent of disease. Although numerous visual assessment

Figure 19.1 Mild to moderate acne.

methods of varying complexity exist, at the basic level they can be subdivided into grades or counts. In both cases, there are three levels at which assessment can be made:

- 1 an overall or “global” evaluation;
- 2 subdivision according to the predominant morphological component (i.e., inflammatory or noninflammatory);
- 3 separate evaluations of individual lesion type (e.g., comedones, papules, and pustules).

The results are generally expressed as an absolute or percentage change from the onset of therapy and are commonly transformed to give the numbers of individuals attaining a given level of improvement; for example, 50%.

Other important outcomes include changes in quality of life, scarring, patient satisfaction, tolerability and adverse events, speed of action, and treatment-free interval.

### Search methods

In the previous edition of this book, this chapter used a systematic review prepared for the Agency for Healthcare Research and Quality (AHRQ) [14] as the primary source of evidence, supplemented by evidence located by searches in the following databases: Cochrane Library (issue 1, 2002), Cochrane Skin Group Specialist Trial Register, Medline (1966 to February 2002), and Embase (1980 to February 2002). The updated chapter includes searches of each of these databases from 2002 to February 2012 for systematic reviews and randomized controlled trials (RCTs).

### Questions

#### Is there any evidence to support the routine use of skin cleansers and/or abrasives in the management of mild to moderate acne?

The impact of detergent bases on the control of sebum has not been ascertained, although it has been hypothesized that removal of

sebum may enhance the activity of topically applied antibacterials. There is also controversy as to whether exfoliation using abrasives clears blocked PSDs and speeds up lesion healing, or whether associated irritancy and drying may aggravate inflamed skin. Antibacterial agents reduce surface bacteria, but there is little evidence to suggest that they penetrate the PSD.

### Efficacy

The AHRQ review included four relevant RCTs [15–17], and additional searches provided four individual trials and a review that included two RCTs [18–22]. Five of the studies were double-blinded (Table 19.1); only two studies enrolled more than 100 patients.

The largest RCT showed that an acidic soap-free syndet was less of an irritant than soap and reduced both ILs and noninflammatory lesions (NILs) in 120 patients with mild acne who were not taking any other anti-acne medication [16]. There were no significant differences between the groups, although the individuals using soap experienced a mean increase in both NILs and ILs over 12 weeks and 23 of 57 experienced irritation, compared with one of 57 in the soap-free group. Similar results were also obtained in more recent studies [21]. A double-blind RCT included 50 patients with moderate acne currently using topical Benzamycin (benzoyl peroxide) or Benzamycin plus adapalene [23]. After 4 weeks of additional treatment with soap or a mild syndet bar, patients using soap had more peeling, dryness, and irritation, whereas those using syndet soap had no significant changes in skin irritation. The mild cleanser was more effective in reducing the severity scores of negative characteristics such as acne, itching, and oiliness. A recent RCT included 13 patients with mild acne [24]. After 8 weeks of treatment with a mild cleanser, patients had a significant decrease in both NILs and ILs. Patients treated with the cleanser plus triclosan, salicylic acid, and azelaic acid, however, showed a significantly larger decrease in ILs both clinically and histologically compared with cleanser alone. These results demonstrate the compatibility between mild cleansers and these various treatment options.

Cleansers containing the antibacterial hexachlorophene produced improvement in equivalent numbers of patients to triclosan in a 12-week crossover trial with 34 patients [15], although no wash-out period was permitted. Eleven patients experienced local reactions to triclosan and nine to hexachlorophene; hexachlorophene is now not recommended. Chlorhexidine was shown to produce equivalent significant reductions in NILs and ILs in 50 patients with moderate acne in comparison with 5% benzoyl peroxide at 12 weeks. It also produced significantly greater reductions in ILs and NILs than in those treated with the vehicle alone in 110 individuals, again at 12 weeks [20]. Chloroxylenol 0.5% in combination with 2% salicylic acid was as effective as 5% benzoyl peroxide in reducing NILs and ILs in 37 patients with mild to moderate acne when applied to the face twice a day [22]. Patients in the combination group experienced significantly less erythema and photosensitivity than those using benzoyl peroxide.

In individuals treated with tetracycline, 500 mg twice daily, additional use of antibacterial soap in a 4-week period offered no benefit over the use of normal soap. However, it was shown to significantly reduce the incidence of acne flare in responders to 4-week tetracycline therapy in a 90-day follow-up (13/30 flared vs 22/31) [19].

After 12–14 weeks in a double-blind RCT, povidone-iodine skin cleanser led to improvement in nine of 10 patients with mild acne, compared with three of seven in the vehicle group. The results are invalidated, however, by the high losses to follow-up [17]. The results in a second group of patients with more severe acne who

**Table 19.1** RCTs of skin cleansers and abrasives.

First author, ref.	Comparators	Patients (n)	Severity	Duration (weeks)	Blinding	Results	Comments
Bettley (1976) [15]	1. Hexachlorophene 2. Triclosan	34	1/2/3	6/6	0	No significant differences; drug improved: 21/28 vs 22/28; local reaction: 11 vs 9	6 LTF; not ITT; crossover study; no wash-out period
Fulghum (1982) [18]	1. Sulfur/salicylic acid cleanser with polyethylene granules 2. Sulfur/salicylic acid cleanser	53	1/2	8	0	Both reduced ILs and NILs; no significant differences; equal sensitivity	7 LTF; not ITT; split half-face study; no concomitant therapy
Kanof (1971, part 2) [19]	1. Antibacterial soap 2. Soap	51	3	>12	A, P	Flare 13/30 vs 22/31	Tetracycline responders; no details on concomitant therapy
Kanof (1971, Part 1) [19]	1. Antibacterial soap 2. Soap	86	3	4	A, P	Response 30/44 vs 31/42	All tetracycline 250 mg 2 or 3 times daily; no details on concomitant therapy; not ITT
Korting (1995) [16]	1. Acidic syndet bar 2. Soap	120	1	12	0	1 reduced ILs and NILs; 2 increased ILs and NILs; no intergroup comparison	2-week wash-out; 6 LTF; ITT analysis; soap 5 dropouts exacerbation; no concomitant therapy
Milikan (1976, A) [17]	1. Povidone-iodine cleanser 2. Vehicle	30	1	12–16	A, P	Improved 9/10 vs 3/7; intolerance 1 = 2	13 LTF; not ITT
Milikan (1976, B) [17]	1. Povidone-iodine cleanser 2. Vehicle	30	2	12–16	A, P	10/13 vs 12/14 improved; 0 intolerance	3 LTF; all tetracycline 250 mg 1 or 2 times daily
Stoughton (1987, A) [20]	1. Chlorhexidine gluconate cleanser 4% 2. Benzoyl peroxide 5%	50	2	12	A	No significant differences in ILs or NILs	3 LTF; not ITT; no concomitant therapy; twice-daily application
Stoughton (1987, B) [20]	1. Chlorhexidine gluconate cleanser 1.4% 2. Vehicle	110	2	12	A	1 = 2 ILs and NILs; dry skin: 3 vs 1	17 LTF; not ITT; no concomitant therapy; twice-daily application
Millikan (1981) [25]	1. Buf-Puf 2. No abrasion	50	2	12	A	No intergroup comparisons; suggestion that abrasion better, but no data	2 LTF; not ITT; all patients received 5% benzoyl peroxide; split-face study
Subramanyan (2004) [21]	1. Benzamycin with or without Differin + soap 2. Benzamycin with or without Differin + syndet bar	50	2	4	A, P	Patients in soap group had increased rates of peeling, dryness Reduced scores for syndet group in itching, acne, and oiliness	
Subramanyan (2003) [23]	1. Current medications + mild cleansing lotion (Dove) 2. Current medications	25	1	4	A, P	Significant reductions in NILs, ILs, erythema, dryness	
Boutli (2003) [22]	1. Chloroxylenol 0.5% + salicylic acid 2% cream 2. BP 5% gel	37	1/2	12	A, P	At week 12, both groups significant in ILs and NILs (60% and 54% for BP group and 56% and 56% for chloroxylenol + salicylic acid group)	Chloroxylenol + salicylic acid slightly stronger keratolytic activity. No difference in reduction of papules. Erythema and photosensitivity significantly lower in chloroxylenol + salicylic acid group

Severity: 1, mild; 2, moderate; 3, severe. Blinding: 0, open; A, assessor; P, patient. BP, benzoyl peroxide; LTF, lost to follow-up; ITT, intention-to-treat; ILs, inflamed lesions; NILs, noninflammatory lesions.

also received tetracycline, 250 mg once or twice daily, were equivocal (10/13 compared with 12/14) [17]. Only one case of mild itching was experienced.

The addition of abrasives to a combination of sulfur and salicylic acid in a split-half-face study in 44 patients did not show any difference in either efficacy or tolerability after 8 weeks. The potential for the effects of the active ingredients to mask all other effects must be considered [18]. One split-face study evaluated the use of addi-

tional abrasion to 5% benzoyl peroxide therapy, but there were no intergroup comparisons to validate the authors' claim that the side of the face treated with abrasion showed better results [25].

### Adverse effects

Soaps are of alkaline pH and are known irritants, causing itching, dryness, and redness; acidic soap-free cleansers may therefore be preferable. Aggressive use of abrasives may irritate skin, and for that

reason common sense suggests that they should not be used in conjunction with topical agents such as benzoyl peroxide, which sensitize the skin, unless tolerance has initially been demonstrated. Dermatological reactions are idiosyncratic and cannot be predicted, and the patient should be advised to discontinue use immediately if irritation develops. Like any topical agent, it is possible that antibacterial cleansers and abrasives are less suitable in individuals with sensitive skin. The literature does not support a link between the use of topical antimicrobials and the emergence of antibiotic resistance [26].

### Comment

The number of propionibacteria on the skin surface is increased by soap and decreased by synthetic detergents [27]. This may be due to the changes in skin pH, which is increased by soap [27]. There is no evidence either for or against the use of abrasive agents, either alone or in combination with topical treatments. There is evidence to suggest that antibacterial skin cleansers may be effective in the management of mild acne [17], and may produce similar outcomes to benzoyl peroxide in moderate acne [20]. However, the long-term benefits of “step-up” management strategies versus aggressive therapy from onset have not been examined. In addition, recent evidence suggests a rebound effect in ILs after discontinuation of cleanser monotherapy [24]. There is no evidence that antibacterial cleansers offer additional benefits when used in conjunction with oral antibiotics in individuals with more severe acne, but they may help maintain improvement following the termination of antibiotic therapy [19]. The impact of increased contact time during washing has not been examined.

### Implications for clinical practice

In individuals with mild acne whose disease is not adversely affecting their quality of life, antibacterial washes should be considered in the choice of first-line management strategies in step-up approaches. They should also be considered in the maintenance of patients who have ceased therapy following response. They should not be prescribed routinely in patients who are receiving more aggressive therapy, as there is no evidence of any additional benefit. Syndet bars may be preferable to soap in skin care routines.

### What is the role of topical nonantibiotic agents in the treatment of mild primarily noninflammatory acne?

Mild acne consisting of open and closed comedones with a few ILs is commonly treated with topical agents. A number of options have been effective in placebo-controlled RCTs, and all can be used either alone or in combination. Options include the topical retinoids (isotretinoin, tretinoin, adapalene, and tazarotene), benzoyl peroxide, salicylic acid, and azelaic acid.

### Topical retinoids

Topical retinoids reduce abnormal growth and development of keratinocytes within the PSD. This inhibits microcomedo formation and therefore subsequently reduces the number of comedones and ILs.

### Efficacy

Evidence for the efficacy of topical retinoids was available from two systematic reviews [14,28], which examined 20 RCTs and split-face studies [29–47]. Fourteen further studies were located through searching [48,49] (Web Table 19.1). Focusing only on comparisons

that had at least two RCTs of acceptable quality showing moderate to strong statistical evidence, the authors of the AHRQ review concluded that 0.1% adapalene and 0.025% tretinoin were equally efficacious and that motretinide and tretinoin were equally effective. The second review [28] evaluated five RCTs of 0.1% adapalene gel versus 0.025% tretinoin [33–35,38,50]. All RCTs were investigator-blind, and a total of 900 individuals with mild to moderate acne were enrolled. Using data collected from intention-to-treat (ITT) analyses, equivalent efficacy against total lesion counts was demonstrated, with adapalene showing greater activity at 1 week.

Of the RCTs that presented data [33,34,37,38,50–54], mean percentage reductions in NILs ranged from 36% to 88% in the 0.1% adapalene group, from 33% to 83% in the 0.025% tretinoin group, and 50% to 86.9% in the 0.05% tretinoin and isotretinoin groups at 12 weeks. Percentage reductions in ILs were 35–69% and 38–71%, respectively. Higher strength adapalene (0.5%) was investigated in one 25-patient split-face study and was shown to have greater activity than 0.1% adapalene against both ILs and NILs, but was associated with more erythema [49]. Two strengths of adapalene (0.1% and 0.03%) were evaluated in five studies enrolling a total of 1053 patients with mild to severe acne [32,33,53–55]. The higher strength produced greater reductions in IL and NIL counts, but was associated with more irritation in some studies, whereas others showed similar rates of erythema.

Topical tazarotene is more effective than other topical retinoids, including adapalene and tretinoin, in the treatment of mild to moderate acne. An RCT compared daily-use tazarotene 0.1% gel with daily 0.1% tretinoin in 169 patients. Tazarotene was more cost effective and was associated with greater reduction of NILs [56]. Both regimens were well tolerated. A meta-analysis of data from multicenter, double-blind RCTs included data on 688 patients who used tazarotene 0.1% gel or cream once daily for 12 weeks. Tazarotene was effective and well tolerated, regardless of the patients' acne severity, skin type, sex, or ethnicity [57]. Another study compared tazarotene monotherapy with three tazarotene combination therapies and clindamycin monotherapy in 440 patients with mild to moderate acne. Tazarotene alone was as effective in reducing NILs as tazarotene in combination with the erythromycin–benzoyl peroxide combination and clindamycin [58]. All tazarotene-containing regimens were more effective than clindamycin alone. For ILs, tazarotene plus erythromycin–benzoyl peroxide combination therapy was significantly more effective than all other treatments.

Recent RCTs show noninferior efficacy of adapalene compared with tazarotene. In an RCT with 160 patients suffering from mild to moderate acne, adapalene 0.3% gel demonstrated similar efficacy in reduction of NILs and ILs compared with tazarotene 0.1% gel. In addition, the adapalene 0.3% gel caused less erythema, scaling, dryness, and stinging/burning [59]. Similar results were demonstrated in an RCT comparing adapalene 0.1% gel with tazarotene 0.1% cream [60]. Another RCT also showed adapalene 0.1% monotherapy equal to “switch therapy” (6 weeks of adapalene 0.1% gel plus 6 weeks of tazarotene 0.1% cream) in a 12-week RCT of 100 subjects with mild to moderate acne, though the study may have been underpowered to evaluate efficacy [61]. Few comparative data for retinoids against other agents were found. In 77 patients with mild to moderate acne, 0.05% isotretinoin applied twice daily was slightly less effective than 5% benzoyl peroxide against ILs and NILs and was slower to resolve ILs [46]. The results for tretinoin against benzoyl peroxide [62–64] were equivocal, and there were no differences in the rate of adverse events. A recent open-label

RCT compared 0.1% adapalene with 4% benzoyl peroxide using percentage clearance as the primary outcome [65]. Both therapies demonstrated similar efficacy, with 78% and 76% of patients showing excellent clearance (60–80% reduction in lesions) in the adapalene and benzoyl peroxide arms, respectively.

### **Adverse effects**

Topical retinoids induce local reactions and should be discontinued if the reaction is severe. All studies presenting data suggested that 0.1% adapalene causes less local irritation than 0.025% tretinoin [49] and that the rate of local reactions with both agents increases with concentration [32,33,49,55,66]. Recent RCTs demonstrated that newer delivery systems of potent topical retinoids, such as tretinoin and isotretinoin, can provide a better tolerability profile than adapalene [67]. Retinoids increase the sensitivity of skin to ultraviolet light and should, therefore, be applied at night and washed off in the morning. Rarely, eye irritation, edema, and blistering of the skin occur, and hypopigmentation may result from tretinoin use.

### **Comment**

There remains uncertainty as to whether retinoids applied topically cause birth defects, and whilst minimal absorption has been demonstrated following topical application [68], as a precaution retinoids should not be used during pregnancy or by women planning pregnancy. Lastly, one large RCT designed to evaluate the efficacy of topical tretinoin for actinic keratoses in an older male population was stopped prematurely due to increased all-cause mortality in the treatment group. Although extensive analysis failed to yield a mechanism for this result other than chance, these results should be discussed with older men using or considering the use of tretinoin [69].

### **Implications for practice**

The comedolytic action of topical retinoids suggests that they should be used in the treatment of mild acne. However, as this activity halts subsequent lesion formation, they are also suitable for moderate to severe acne and can be used in conjunction with topical and oral antibiotics. Benzoyl peroxide inactivates tretinoin, so the two agents should not be applied simultaneously; if used in combination, one should be applied in the morning and one at night. All topical retinoids cause local sensitivity reactions, which are less common with adapalene. To limit local sensitivity, topical retinoid therapy should start at a lower strength, be applied every third night, and increase gradually.

### **Benzoyl peroxide**

The lipid solubility of benzoyl peroxide allows it to penetrate the PSD. It has comedolytic, anti-inflammatory, and bactericidal activity and is therefore suitable for management of individuals with mild inflammatory or mixed acne. It can be bought over the counter from pharmacies and is available in a number of formulations, in strengths of 2.5–10.0%.

### **Efficacy**

The AHRQ systematic review [14] examined seven placebo-controlled RCTs in patients with mild to severe acne [46,70–75] (Web Table 19.2). Changes in both NILs and ILs were consistently significantly superior in the active group. Two RCTs reported mean reductions in lesion counts with 5% benzoyl peroxide: 52% and 60% for ILs and 30% and 52% for NILs [46,72]. The reductions in

the vehicle comparator arms were less than 10% in each case. Four RCTs compared different dosages of benzoyl peroxide [62,70,76], and no evidence was found to support a dose–response effect (Table 19.2).

Three RCTs compared topical tretinoin with 5% benzoyl peroxide [63,64,77]. Tretinoin was more effective against NILs up to 12 weeks, but benzoyl peroxide had a greater impact on ILs. Another trial compared 2.5% benzoyl peroxide, 0.1% adapalene, 0.1% adapalene/benzoyl peroxide combination, and vehicle [78]. Combination therapy was significantly more efficacious in reducing total lesions than any other tested treatment, showing a 62.1% reduction in ILs and a 53.8% reduction in NILs at 12 weeks. Benzoyl peroxide monotherapy ranked second efficacious with a 50% reduction in ILs and a 49.1% reduction in NILs.

A recent split-face RCT compared solubilized 5% benzoyl peroxide gel to 5% benzoyl peroxide/1% clindamycin in 23 patients with moderate acne [79]. With 4 weeks of therapy, patients demonstrated a mean reduction of 42% and 28% of NILs in the solubilized benzoyl peroxide arm and the benzoyl peroxide/clindamycin arm, respectively. In addition, there was a 70% reduction in ILs with solubilized benzoyl peroxide and a 61% reduction in ILs with benzoyl peroxide/clindamycin. Studies also show that 5% benzoyl peroxide has similar efficacy to 20% azelaic acid in mild acne [80].

A recent meta-analysis of 23 RCTs including 7309 patients compared benzoyl peroxide in combination with salicylic acid or clindamycin with benzoyl peroxide and clindamycin monotherapy. Benzoyl peroxide plus salicylic acid proved most efficacious in the reduction of NILs and ILs at early time points (2–4 weeks). Benzoyl peroxide plus salicylic acid and benzoyl peroxide plus clindamycin demonstrated similar results at later time points (10–12 weeks). Though large, the study is of moderate clinical use owing to possible selection bias and the lack of patient-oriented outcomes. In addition, it is questionable how much combination therapy improves efficacy over monotherapy [81].

### **Adverse effects**

Benzoyl peroxide is commonly associated with local irritation that presents as erythema, peeling, dryness, burning, stinging, itching, and soreness. Use of an emollient or water-based gel may reduce these reactions. Recent RCTs also demonstrate that new benzoyl peroxide delivery systems, such as combination products with urea as well as microparticle benzoyl peroxide, minimize noxious side effects while maintaining efficacy [82]. However, these new preparations have not been rigorously evaluated [83]. Allergic contact dermatitis, characterized by erythema, small papules, and pruritus, may occur rarely. RCT evidence shows that the side-effect profile of a 2.5% preparation is similar to that of 5% [70,76] and less than 10% preparations [70]. Combinations of benzoyl peroxide with antibiotics are unstable because of degradation of the antibiotic by benzoyl peroxide. Benzoyl peroxide will bleach hair and fabrics, and patients should therefore be counseled accordingly. It is safe for use during pregnancy. There were concerns that benzoyl peroxide might promote skin cancer [84,85], but these have been refuted [86].

### **Comment**

A major concern with the continued use of antibiotics, topical and oral, is the promotion of *P. acnes* resistance. Benzoyl peroxide has a broad-spectrum bactericidal action, which does not select for resistance during long-term use. It is therefore recommended that it is used intermittently during courses of antibiotics, to eliminate any resistant propionibacteria [87,88].

**Table 19.2** Benzoyl peroxide (BP) dose–response RCTs.

First author, ref.	Comparators	Patients (n)	Severity	Duration (weeks)	Blinding	Outcomes	Comments
Mills (1986, 2) [70]	1. BP 2.5% 2. BP 5%	53	1/2	8	P, A	Equivalent efficacy and burning, peeling and erythema; ILs: 56% vs 58% reduction	2 LTF; not clear if randomized

Fyrand (1986) [297]	1. BP 5% (alcohol) 2. BP 5% (water)	48	—	8	P, A	No difference in clinical effect, but less irritation with water-based preparation	Abstract only

Severity: 1, mild; 2, moderate; 3, severe. Blinding: 0, open; A, assessor; P, patient. BP, benzoyl peroxide; LTF, lost to follow-up; ITT, intention-to-treat; ILs, inflamed lesions; NILs, noninflamed lesions; SSD, statistically significant difference.

### Implications for practice

Benzoyl peroxide alone or in combination with other topical treatments is the standard of care for mild to moderate acne vulgaris, as a result of its activity against both ILs and NILs. Some individuals find benzoyl peroxide highly irritating on initial application. Tolerance is generally developed with prolonged exposure, and individuals should be counseled accordingly. Low-strength benzoyl peroxide is recommended, as higher strengths are more of an irritant and there is no evidence to suggest that 10% in general is more effective than 5%. Recent evidence suggests that newer delivery systems may mitigate intolerable side effects. It is common practice for patients to apply benzoyl peroxide to individual lesions alone; clinicians should advise patients to apply it in a thin layer to all areas to prevent the formation of new lesions.

### Salicylic acid

Salicylic acid is an exfoliant and chemical irritant.

#### Efficacy

The AHRQ review [14] located three RCTs (Table 19.3) [88–90]. Two percent salicylic acid was more effective in reducing all lesion types than the alcoholic lotion vehicle at 12 weeks in 114 paired individuals with mild to moderate acne [88]. The second study enrolled 30 individuals and had major losses to follow-up [90]; 1.5% salicylic acid was more beneficial than placebo. One further crossover RCT in 30 individuals with mild acne compared a 2% cleanser with a 10% benzoyl peroxide facial wash; neither product was therefore in prolonged contact with the skin [89]. The results of the study cannot be considered as valid evidence, however,

because the trial was only 4 weeks in total and there was no wash-out period between the 2-week treatment periods.

#### Adverse effects

Salicylic acid is known to cause skin irritation that presents as erythema, dryness, and peeling; this was evident in the RCT evidence located.

### Implications for practice

There is no evidence to support the routine use of salicylic acid in preference to other topical therapies.

### Azelaic acid

Azelaic acid has been shown to normalize the increased keratinocyte production and keratinization associated with acne and to inhibit *P. acnes* [91]. A direct anti-inflammatory effect has also been demonstrated [92].

#### Efficacy

The AHRQ review [14] located eight RCTs of azelaic acid in mild to moderate acne (Web Table 19.3). The comparators used were placebo [93], vehicle [94], benzoyl peroxide [77], tretinoin [94], oral tetracycline [95,96], and in combination with glycolic acid versus tretinoin [97]. One further RCT published in German evaluated its efficacy against 2% erythromycin [98,99].

In papulopustular acne, 20% azelaic acid has similar efficacy at 5 or 6 months to 0.05% tretinoin [94], 5% benzoyl peroxide [80], 2% topical erythromycin [99], and oral tetracycline 1 g/day [95,96], with consistent percentage reductions in median ILs of 80–84%. In

Table 19.3 RCTs of salicylic acid.

First author, ref.	Comparators	Patients (n)	Duration (weeks)	Severity	Blinding	% decreased NIL	% decreased IL	Outcomes	Comments
Shalita (1981) [89]	1. Salicylic acid 2% cleanser	30	2 + 2	1/2	0	34		No side effects reported	Crossover; no wash-out period; no LTF; results not valid as phase 1 only 2 weeks and no wash-out period; BP group higher NIL count at baseline; short contact
	2. BP 10% wash					20			
Eady (1996) [66]	1. Salicylic acid 2%	114	12	1/2	A,P	46*	28*	1 > 2 all lesions; irritant dermatitis both groups but greater incidence in 1; percentage decrease total lesions: 40 vs 16*	15 LTF; not ITT; both in alcoholic lotion
	2. Vehicle					26	9		
Roth (1964) [90]	1. Salicylic acid 1.5%	30	10	1/2	0			Salicylic acid reported as greater reduction, but no intergroup comparison; burning in 10/15 in salicylic acid group	
	2. Placebo								

\* Statistically significantly superior ( $P < 0.05$ ).

Severity: 1, mild; 2, moderate; 3, severe. Blinding: 0, open; A, assessor; P, patient; BP, benzoyl peroxide; LTF, lost to follow-up; ITT, intention-to-treat; ILs, inflamed lesions; NILs, noninflamed lesions.

comedonal acne, 20% azelaic acid had similar activity to 0.05% topical isotretinoin, with 79% and 82% reductions in comedonal counts, respectively. A multicentered RCT of 150 patients with mild-to-moderate acne compared 5% azelaic acid and 2% azelaic acid/clindamycin combination. The combination therapy showed a significant reduction in acne severity index (64.16%) compared with either 5% azelaic acid (32.46%) or clindamycin monotherapy (47.73%) after 12 weeks [100]. Similarly, combination 5% azelaic acid and 2% erythromycin yielded significant lesion reduction compared with azelaic acid or erythromycin monotherapy [101].

### Adverse effects

In common with other topical agents, azelaic acid induces cutaneous reactions, which occur in approximately one-third of individuals [99]. The incidence is highest in the first 4 weeks of therapy and, in the RCTs examined, only 5–10% of reactions were categorized as “marked.” In the clinical studies, which also included postmarketing evaluations, 0–5% of individuals experienced scaling, 5–23% burning, and 13–29% itching. Azelaic acid is not known to cause photosensitivity, and sublethal doses do not promote *P. acnes* resistance [102]. Azelaic acid is better tolerated than benzoyl peroxide [80] and tretinoin [94,97], and it does not bleach clothing or hair. It is used in hyperpigmentary skin disorders, but has not been shown to have depigmentary effects in acne patients [102], suggesting that it preferentially targets abnormal melanocytes.

### Comments

There are no known incompatibilities between azelaic acid and other topical anti-acne agents.

### Implications for practice

Azelaic acid is an effective therapy for mild to moderate papulopustular acne and as effective as 0.05% isotretinoin in comedonal acne. The onset of action is slower than that seen with benzoyl peroxide. Patients should be counseled to expect a delayed response. Anecdotal reports have suggested that azelaic acid may reduce the incidence of postinflammatory hyperpigmentation, which is possibly attributable to its activity on abnormal melanocytes [103]. Darker skinned patients should be monitored for signs of hypopigmentation.

### Summary

All of the agents reviewed are effective in the treatment of mild and moderate acne vulgaris. There are very few data to support the use of one agent over another, and there has only been one RCT on the use of the agents in combination, which showed that benzoyl peroxide and tretinoin in combination are superior to either agent alone [62]. Adapalene is better tolerated than tretinoin, and the RCT evidence reviewed suggests that azelaic acid may be better tolerated overall than other agents, but there will be considerable variation between individual patients. A number of RCTs compare these agents against and in combination with topical antibiotics; these are considered in the next section.

### What is the role of antibiotics in the management of acne vulgaris?

The role of antibiotics in the management of acne is still debated, and although much evidence has been collected on the efficacy of individual agents, there are very few good-quality comparative data. Oral antibiotics were used initially in the 1950s because it was assumed that acne occurred as a result of bacterial infection. Whilst activity against *P. acnes* has been clearly demonstrated, there is evidence of an anti-inflammatory effect [104], which is still being investigated.

Three systematic reviews provided evidence on the role of antibiotics [14,105,106]. The conclusions of the AHRQ review are based only on comparisons, where there are at least two trials of acceptable quality showing moderate to strong statistical evidence for a clinically meaningful end point and effect. Of the oral antibiotics, the only clear evidence was located for tetracycline. Topical clindamycin and erythromycin were superior to vehicle in the treatment of mild to moderate acne, and topical tetracycline was ineffective. The Cochrane review [105] of minocycline examined 27 RCTs and concluded that while minocycline is likely to produce similar outcomes to other first-generation and second-generation tetracyclines, it should not be used as a first-line agent, because of uncertainty over its safety and higher cost in comparison with older tetracyclines. There was no evidence to suggest that it is superior to other tetracyclines, and its efficacy relative to other acne therapies could not be reliably determined because of inadequacies in

the studies examined. The third systematic review [106] evaluated all randomized and nonrandomized clinical trials ( $n = 45$ ) investigating topical therapy with erythromycin or clindamycin alone for inflammatory acne. A significant decrease in the treatment effect of topical erythromycin occurred over time, suggesting the development of antibiotic resistance.

### Oral antibiotics

The AHRQ report reviewed 11 placebo-controlled trials of oral antibiotics [107–117], and five others were located by searches [118–122] (Web Table 19.4). All but five RCTs investigated tetracycline; one evaluated minocycline, two doxycycline [123], one roxithromycin [120], and one lymecycline [121]. All were double-blinded, and most included patients with moderate to severe acne. Only five provided data at 12 weeks or more [110,113,114,121,122], and only four included more than 50 patients in each arm [114,116,118,121]. Tetracycline at total daily doses of 500 mg and 1 g was consistently superior to placebo in terms of overall grade and reduction in ILs. Lymecycline 150 mg b.i.d. and lymecycline 300 mg q.o.d. were equally efficacious in the treatment of moderate to severe acne, and both were superior to placebo at all points during a 12-week study [121]. A small RCT ( $n = 46$ ) reported a significant decrease in median acne scores in comparison with placebo in patients taking roxithromycin 150 mg b.i.d. during the 10-week study. Data on NILs were from two doxycycline RCTs [122,123]. One reported comparable efficacy [123] at 4 weeks, but this is expected, given the delayed onset of activity associated with oral antibiotics. A second RCT designed to evaluate subantimicrobial dosing of doxycycline (20 mg b.i.d.) showed statistically significant decreases in ILs, including an 84% reduction in papules and a 90% reduction in pustules at 3 months [124].

Nine head-to-head RCTs of the currently used oral antibiotics were included in the AHRQ review [125–133]; the Cochrane review located a further nine [134–142], and further search located three additional studies [143–145] (Web Table 19.5). The majority of the trials had problems with design and execution. No oral antibiotic was demonstrated to be superior to any other, although equivalence cannot be conclusively stated, as none of the studies was adequately powered to demonstrate it. Percentage reductions in ILs were consistently greater than 50% at 12 weeks. Percentage reductions in NILs were more variable, with only three RCTs reporting more than 50% reductions at 12 weeks [139,142,144]. The results consistently showed an improvement in 70–90% of individuals at 12 weeks. A recent multicenter RCT showed that minocycline 100 mg daily, roxithromycin 150 mg b.i.d., and faropenem 200 mg t.i.d. were equally as efficacious in terms of IL reduction and safety after 8 weeks in patients with moderate-to-severe acne [145]. Similar to previous studies, this RCT was not adequately powered to evaluate equivalence. Conversely, a systematic review of 57 RCTs demonstrated a high-quality analysis of oral tetracyclines and showed equal efficacy in the reduction of both NILs and ILs [146].

### Topical antibiotics

The AHRQ review located 31 RCTs comparing a topical antibiotic with its vehicle, and a further eight RCTs were located by independent searches (Web Table 19.6). Nine of the RCTs also included other comparators. The antibiotics investigated were clindamycin (13 RCTs) [75,115,116,147–156], erythromycin (14 RCTs) [157–165], erythromycin/zinc (three RCTs) [117,166,167], 2% fusidic acid (two RCTs) [168,169], meclocycline [170], metronidazole [171], triclosan [172], and tetracycline (three RCTs) [112–114]. Among

the studies for which details were available, all but two used twice-daily application [75,156]. Many of the studies were underpowered to conclusively state that there were no significant differences between the comparators. A systematic review [106] designed to assess the efficacy of the topical antibiotics erythromycin and clindamycin over time included 45 studies: 22 double-blind ITT studies, 10 placebo-controlled trials, 12 single-blind trials, and 1 open, randomized trial. The duration of treatment in the trials included varied between 8 and 12 weeks for erythromycin and between 8 and 16 weeks for clindamycin, with 12 weeks being most common for both medications. Erythromycin concentrations varied in studies from 1.5% to 4% (most common concentrations were 1.5% and 2%), while clindamycin concentrations remained stable during the analysis period at between 1% and 1.2%. Comparisons of studies longitudinally only included trials using the same antibiotic dosage.

The AHRQ review concluded that although clindamycin tended to produce greater reductions in ILs than its vehicle, the results were rarely statistically significant; global measures more consistently indicated superiority to placebo. The evidence available does not support the effectiveness of clindamycin against NILs. Erythromycin similarly had a greater impact on ILs. A 12-week study of clindamycin 1% foam versus clindamycin 1% gel applied once daily also included vehicle comparators [156]. This study reported a statistically significant advantage in total lesions, ILs, and NILs with foam over gel and superior efficacy in comparison with the vehicle. A 24-week study of 2% erythromycin gel versus vehicle, designed primarily to detect bacterial resistance to treatment over time [165], found no difference in acne outcomes at any point during the study. Highly resistant erythromycin-specific susceptibility profiles were found among patients randomly assigned to the erythromycin treatment arm. Fusidic acid was more active than vehicle against ILs at 6 weeks in one study, but not at 12 weeks in a second study, which also did not show any difference in its activity against NILs. The two meclocycline studies also showed decreases in ILs, with no data for NILs. The 0.75% metronidazole RCT showed that it was no more active than placebo in mild to moderate acne, producing statistically significant reductions in neither ILs nor NILs. The three tetracycline RCTs demonstrated that 0.5% tetracycline was approximately 50% more active than vehicle in terms of change in acne grade from baseline, although no intergroup statistical analyses were performed. Only one trial provided data on differential lesion counts; the results suggested again that tetracycline was active against ILs but not NILs. In the larger RCTs, a 55–60% mean reduction in ILs was consistently seen at 12 weeks [14].

The AHRQ review located 14 head-to-head trials of topical antibiotics, and further search yielded four additional RCTs (Web Table 19.7). There were no differences in efficacy between clindamycin hydrochloride and phosphate [150,151,155], or between different formulations [154,173,174] in the six RCTs examined in the AHRQ. One RCT did demonstrate a difference between clindamycin formulations, showing clindamycin 1% foam to be superior to clindamycin 1% gel for reduction of total lesions, ILs, and NILs at 12 weeks [156]. Four large RCTs [167,175–177] and one smaller study [178] compared clindamycin and erythromycin. Several trials reported differences between topical antibiotics for certain outcomes at certain time points, though there were no consistent differences overall. Topical 0.3% ciprofloxacin showed greater efficacy to 4% erythromycin in percentage pustule reduction over 6 weeks, providing evidence for an alternative topical therapy when bacterial resistance is considered [179]. Similar efficacy of topical fluoroqui-

nolones in mild to moderate acne was demonstrated in an RCT comparing 1% nadifloxacin cream with 4% erythromycin gel [180]. In comparison with tetracycline, two studies [181,182] reported insignificant or inconsistent differences in lesion counts. However, both trials demonstrated a significant difference in favor of clindamycin in terms of acne severity or improvement. No difference between clindamycin and nicotinamide was shown in the RCT located, but it was underpowered to conclusively state equivalence [183]. An additional 12-week RCT [184] compared a 2% topical azithromycin preparation with a 2% topical erythromycin. Comparable decreases in ILs counts were seen in both groups, though the study was underpowered and not placebo controlled. One systematic review [106] evaluated RCTs comparing the efficacy of erythromycin versus clindamycin. Though topical erythromycin remains a viable treatment option, a significant decrease in efficacy has occurred over time (1974–2002), while the efficacy of topical clindamycin remained stable.

### Oral versus topical antibiotics

The two systematic reviews located also provided comparative data on the use of oral versus topical antibiotics [14,105]. A number of other nonsystematic reviews and individual RCTs were also located, giving a total of 21 studies [161,185–198], six of which also included a placebo control arm [112–117] (Web Table 19.8). Twelve used double-dummy designs to maintain blinding. Oral antibiotics have a delayed onset of activity; studies of shorter duration may therefore be biased in favor of the topical agent.

The evidence from three RCTs suggests that minocycline, 50 mg twice daily, produces results against both NILs and ILs that are comparable with 1% clindamycin applied twice daily [191,193]. All but one trial [198] enrolled fewer than 100 patients, and they were therefore underpowered to conclusively state equivalence.

Six RCTs compared oral tetracycline 250 mg twice daily with 1% clindamycin twice daily [115,116,161,185,187]. Only one RCT was longer than 8 weeks in duration [187], and only one study was adequately powered (305 patients), but it was of inadequate duration [116]. This study found that at 8 weeks there was no significant difference in the percentage reductions obtained with either tetracycline 250 mg twice daily or 1% clindamycin applied twice daily in pustules (68% vs 76%) and papules (63% vs 68%) in patients with moderate to severe acne. However, the physician rated the clindamycin therapy as good to excellent in a greater number of cases: 86 of 105 in comparison with 66 of 103 ( $P < 0.05$ ). Four of the other studies failed to detect any significant differences between the therapies, with the fifth finding that clindamycin caused significantly greater percentage reductions in ILs (57% vs 72%;  $P < 0.001$ ) at 8 weeks in patients with mild acne [115]. The 12-week study found no difference [187].

Tetracycline, 250 mg twice daily, produced similar changes in lesion counts at 12 weeks to topically applied 1.5% erythromycin in a single RCT of 54 patients with moderate to severe acne [190]. Although erythromycin produced greater percentage changes numerically, these were not significant. None of the four RCTs located found any differences in overall grade between oral tetracycline, 250 mg twice daily, and topically applied 1.5% meclocycline twice daily; both were superior to placebo in the three studies that also used a placebo control [189]. None of the studies used ITT analysis. At 8–12 weeks, oral tetracycline 250 mg twice daily was found to produce similar reductions in overall grade to topical 0.5% tetracycline, with one trial finding no effect on comedones [112–114].

### Combination therapy

A number of RCTs have investigated oral and topical antibiotics either against or in combination with other agents (Web Table 19.9), the rationale for this being that treatments that attack more than one factor implicated in the pathogenesis of acne will be more effective. The different mechanisms of action are summarized in Table 19.4 [199].

### Efficacy

Two RCTs were located that compared an oral antibiotic with benzyl peroxide [196–198]. Although one study was underpowered to conclusively state equivalence, similar efficacy was found between 5% benzyl peroxide and oral oxytetracycline, 250 mg twice daily, at 6 weeks [197]. The oral agent was more effective against acne of the trunk. A large ( $n = 649$ ) randomized 18-week study compared five antibacterial regimens: oxytetracycline plus topical placebo; oral Monocline (doxycycline) plus topical placebo; topical benzyl peroxide plus oral placebo; topical erythromycin and benzyl peroxide combination plus oral placebo; and topical erythromycin and benzyl peroxide separately plus oral placebo [198]. Topical benzyl peroxide and benzyl peroxide–erythromycin combinations showed similar efficacy to oral oxytetracycline and minocycline.

The AHRQ review located eight RCTs that compared topical antibiotics with 5% benzoyl peroxide, and searches found one additional trial [75,164,196,200–204]. In the three RCTs located, 5% benzoyl peroxide was found more active against NILs in moderate acne than 1% clindamycin [75,200,201] over 10–12 weeks. Two studies also found that it was more active against ILs [200,201], although the third found no difference [75]. Benzoyl peroxide was also more active against both NILs and ILs than 1% meclocycline [203]. Compared with erythromycin, benzoyl peroxide was more active against NILs and similarly active against ILs [164,202]. All RCTs providing data showed that benzoyl peroxide caused more local irritation.

Three RCTs compared 20% azelaic acid with oral tetracycline (variable dose) [95,96] in patients with mild to severe acne. No significant differences were reported in any lesion counts, except in the smallest trial, which was very small and suffered from high drop-out rates in the azelaic acid group. A 20-week RCT of 20% azelaic acid in comparison with 2% topical erythromycin was located through additional searches [98]. No differences between the comparators were found.

**Table 19.4** Targets of acne therapies.

	Sebum excretion	Keratinization	Follicular <i>P. acnes</i>	Inflammation
Benzoyl peroxide	–	(+)	+++	(+)
Tretinoin	–	++	(+)	–

### Use of combination therapies

Twelve RCTs were located that examined combinations of 0.025% tretinoin and 1–1.2% clindamycin against either tretinoin, clindamycin [205,206], or both [207–211] (Web Table 19.10). One additional RCT compared a combination 2% erythromycin–0.05% tretinoin against each agent individually [212]. The combination therapy clindamycin–tretinoin produced a greater reduction in NILs and ILs, though statistical significance was only reached with clindamycin and tretinoin monotherapy, respectively [205,206,210,211]. Three additional studies evaluated the role of adding benzoyl peroxide to a tretinoin and clindamycin regimen. One study reported similar efficacy and improved tolerability of clindamycin–benzoyl peroxide compared with clindamycin–benzoyl peroxide in the morning plus tretinoin and clindamycin in the evening [209]. The two remaining studies showed that clindamycin–benzoyl peroxide induced a more rapid clearance of NILs and ILs [213] as well as reduced *P. acnes* colonization and antimicrobial resistance [214] compared with a benzoyl peroxide-deficient clindamycin and tretinoin scheme.

Four trials compared 0.1% adapalene plus antibiotic combinations to antibiotic alone [215–218]. In the first trial of 242 patients with moderate to severe acne, adapalene plus 300 mg of lymecycline showed a greater reduction in NILs and ILs at 12 weeks than lymecycline plus vehicle. Side-effect profiles were similar for both treatment groups [215]. The second trial included 467 patients with severe acne who were randomly assigned to either the adapalene plus doxycycline group or doxycycline treatment alone for 12 weeks. Percentage reductions in NILs were 60% and 41% respectively [216]. There was also a greater reduction in the combination group for ILs (65% vs 59%). Both treatments were well tolerated. The third and fourth trials compared the efficacy of clindamycin alone and in combination with adapalene in a total of 549 patients with mild to moderate acne [217,218]. Both trials showed significant reductions in NILs and ILs in the combination group by week 12. The fourth trial also demonstrated a significant reduction in all lesion counts during the maintenance phase in patients receiving adapalene (42%) in comparison with an increase for all lesion counts in the control group (92.1%). A fifth trial that compared a retinoid in combination with an antibiotic with 5% benzoyl peroxide in combination with 3% erythromycin in 188 patients with mild to moderate acne showed comparable efficacy after 12 weeks [219].

One 12-week RCT compared topical 5% dapsone gel plus 0.1% tazarotene cream with tazarotene monotherapy [220]. Though both combination and monotherapy demonstrated a significant reduction in lesion count from baseline, the combination therapy showed a greater reduction in NILs while maintaining a similar side-effect profile. This study provides moderate evidence for the use of dapsone–tazarotene combination in early comedonal acne. No patients experienced systemic side effects of dapsone.

A trial that compared a hydrogen peroxide cream and 0.1% adapalene gel combination with a benzoyl peroxide cream and adapalene gel combination showed equivalent reductions in NILs [221]. Significant reductions in ILs and better tolerability were noted for the hydrogen peroxide plus adapalene group at week 8 in patients with mild to moderate acne. The use of adapalene and benzoyl peroxide alone and in combination reduced NILs and ILs at 24 weeks, with no significant differences in erythema, dryness, or burning.

Combinations of antibiotics and benzoyl peroxide were examined in 10 RCTs (Web Table 19.11); the antibiotics were clindamycin [75,191,222], erythromycin [164,223–226], meclocycline [203], dapsone, and metronidazole [204]. In the seven studies that used

an antibiotic alone as a comparator, the combination was more active against both ILs and NILs [75,164,200,222,223,227]. In the seven studies that used benzoyl peroxide alone as a comparator [75,164,200,203,204,226], the data were equivocal; some studies showed a greater effect for the combination therapy while others showed no statistical difference [75,164,200,203,204,222,226]. The most recent study showed similar side-effect profiles between the combination therapy and the monotherapies [222]. The trial comparing 5% dapsone gel plus benzoyl peroxide with dapsone plus moisturizer showed no statistical difference in reduction of ILs [228]. Combination 5% benzoyl peroxide–3% erythromycin has greater activity against *P. acnes* than 3% erythromycin monotherapy and results in significantly greater clinical improvement [88]. One 8-week RCT [229] of 327 patients with moderate to severe acne demonstrated that a new single-use erythromycin–benzoyl peroxide formulation reduced acne lesions in terms of the physicians' global acne severity scores and the patients' end-of-treatment global assessment of improvement. Since refrigeration is not required, patients can mix the two gels in the single-use package and eliminate the need for a compounding pharmacist.

Another study compared 5% benzoyl peroxide plus 2% metronidazole against an oral antibiotic (oxytetracycline); however, the results of this trial were unfairly biased against the oral antibiotic due to the short 6-week duration of the study [204]. Another RCT of adequate duration (16 weeks) compared concomitant 5% benzoyl peroxide with an oral antibiotic (oxytetracycline 0.5 g, 1 g, and 1.5 g), but this study did not clearly state whether or not patients were randomized to treatment [230]. The response was considered adequate in 2 of 23 patients with 5% benzoyl peroxide monotherapy and in 6 of 24, 8 of 19, and 12 of 17 patients using 5% benzoyl peroxide plus oxytetracycline 0.5 g, 1 g, and 1.5 g, respectively. A recent RCT suggested the addition of levamisole to doxycycline regimens for severe nodulocystic acne [231]. The patients receiving doxycycline 100 mg daily plus levamisole 2.5 mg/kg per week demonstrated a significant decrease in ILs (nodules+cysts: 90%) as well as acne severity index (82.2%) compared with doxycycline monotherapy (nodules+cysts: 58%; acne severity index: 67.95%).

Few studies have compared oral antibiotic treatment regimens with oral retinoids. A recent 6-month RCT with a 2-month follow-up compared oral tetracycline plus topical adapalene with oral isotretinoin [232]. Though both arms led to decreased NILs and ILs from baseline, oral isotretinoin demonstrated an increased reduction of NILs and superficial ILs while maintaining a prolonged improvement after treatment cessation. Nonetheless, oral tetracycline plus topical adapalene was revealed as a comparable treatment option if oral retinoids are contraindicated.

### Harms

All antibiotics are associated with individual side effects that are well documented and must be considered. The potential systemic side effects are theoretically reduced by topical application, as usually less than 10% absorption occurs [233]. However, prolonged and extensive application to the skin, which is a good medium for gene exchange amongst bacteria [234], may facilitate the spread of resistance [235]. This has implications for clinical practice, as *P. acnes* resistance is associated with a poor therapeutic response to antibiotics, and the efficacy of some antibiotics is decreasing over time. Of greater importance, however, is the spread of resistance to other microorganisms, and there have been calls for policies to restrict the prescribing of antibiotics in acne [87,236]. In particular, studies have shown that both *P. acnes* and *Staphylococcus epidermidis* can transfer antibiotic resistance to *Staphylococcus aureus*

[83]. One systematic review examined *P. acnes* resistance to systemic antibiotics [237]. The 12 articles examined demonstrated an overall increase in *P. acnes* resistance, from 20% in 1978 to 62% in 1996. Resistance was most commonly reported to erythromycin, clindamycin, tetracycline, doxycycline, and trimethoprim; resistance to minocycline was rare. The authors concluded that long-term rotational antibiotics are inappropriate and that treatment should be adjusted when therapeutic failure becomes evident. Antibiotic–benzoyl peroxide combination therapies can be useful, as these regimens were not affected by *P. acnes* antibiotic resistance [198], and have been shown to reduce the concentration of antibiotic-resistant *P. acnes* on the skin prior to treatment and the emergence of new antibiotic-resistant *P. acnes* posttreatment initiation [83,214].

### Comment

A proportion of individuals fail to respond to antibiotics; epidemiological studies have estimated that the figure is between 10% [238] and 17% [239] of individuals. Theories that have been proposed include individual differences in the absorption, distribution, and elimination of the antibiotic, as well as poor compliance, the follicular microenvironment, and *P. acnes* resistance [238]. The underlying severity of the disease may also determine the response to antibiotics, as severe acne and acne of the trunk have been shown to respond less well than moderate acne [239,240], possibly as a result of the higher sebum excretion rate (SER) [241] diluting follicular drug concentrations [238]. Clinically, another important impact of alteration in cutaneous microflora is the possibility of Gram-negative folliculitis developing, which presents with profuse superficial pustules around the nose and deep cystic lesions on the face and neck, usually colonized by *Proteus*, *Enterobacter*, or *Klebsiella* species [242].

### Implications for practice

There is no conclusive evidence of the superiority of one antibiotic over another, nor of any advantages for either oral or topical application. The choice of agent should, therefore, be based on the patient's preference, with consideration of the individual side effects of the antibiotics and the cost. The formulation of the topical antibiotic may also be important – for example, alcohol bases are likely to be more drying and, therefore, more suitable for oilier skins. Patients with more extensive disease, particularly those with acne of the trunk, may prefer oral treatment rather than having to apply topical agents to extensive areas. It is vital that patients should be properly counseled on how to use their medication, as inappropriate use has been shown to reduce effectiveness [230].

Second-generation tetracyclines – such as minocycline, doxycycline, and lymecycline – have been described as being more active, because their greater lipophilicity results in greater sebum penetration and PSD concentration. This review has not found any evidence to support this, and their superiority has not been demonstrated. These agents are easier for patients to take, however, as they can be taken once daily and the absorption may be less affected by food [243–245]. However, tetracycline need not be taken four times a day: its half-life of approximately 9 h in plasma is likely increased in the skin. Furthermore, subantimicrobial doses of doxycycline may be as effective as standard dosages. Maintaining serum antibiotic concentrations at steady state does not appear necessary for clinical efficacy or moderating anti-inflammatory effects.

It is recognized that antibiotics have less activity than other agents against NILs, which makes them less suitable for use in

patients with primarily noninflammatory acne. The evidence for the comparative efficacy of antibiotics and benzoyl peroxide against ILs is equivocal, and further research is required to establish their relative place in acne therapy. The studies reviewed found that combinations of antibiotics with benzoyl peroxide were more effective than antibiotics alone, which can probably be attributed in part to the lack of activity of antibiotics against NILs. However, the irritancy of benzoyl peroxide may make it unacceptable to some patients. There is no compelling evidence for the combined use of antibiotics and retinoids. There is no benefit in concomitant use of oral and topical antibiotics, and this practice may select for resistant strains. Intermittent use of benzoyl peroxide is recommended during extended antibiotic therapy, to eliminate any resistant strains [246]. If antibiotic resistance is a major concern, another viable option would be to discontinue antibiotics altogether and start a combination topical therapy, such as benzoyl peroxide and a topical retinoid [247]. Though the evidence is sparse, this approach has been shown to reduce antibiotic-resistant *P. acnes* after 4 weeks of treatment [247].

### What dose of oral antibiotics should be prescribed?

Historically, antibiotics have been used for the treatment of acne vulgaris at doses that are lower than those used for other infections. Although the exact origin and rationale of this convention is not known, the most likely explanation is that doses were reduced initially in response to concerns over maintaining patients on high-dose antibiotics for long periods of time. When it was subsequently observed that lesions did not recur when the dose was reduced and that patients relapsed as soon as therapy was discontinued, dose reduction would have become standard practice [248]. Low doses of antibiotics were therefore used in early trials [110,119,249,250]. Guidelines recommended that full antibiotic doses should be used initially for 3–4 weeks and then reduced gradually until the patient can be maintained on the lowest possible dose [251,252]. Despite the fact that there are no adequate dose–response studies to support it, this use of low-dose antibiotics has remained standard practice for many years.

Only four RCTs were located that investigated the use of different doses of antibiotics. One study failed to find any clinical difference after 8 weeks of therapy between patients maintained on an initial starting dose of minocycline 100 mg daily and those in whom the initial dosage was reduced to 50 mg daily after 4 weeks [253]. Minocycline may not be typical of all antibiotics, however, because there is considerable variation between individuals in the serum levels attained after oral administration [254]. Eight weeks may also be an inadequate period to examine comparative efficacy. In the second study, roxithromycin 300 mg was more effective than 150 mg over 8 weeks in 30 patients with severe acne [255]. A third study evaluated subantimicrobial doses of doxycycline (20 mg b.i.d.) in comparison with placebo for 6 months and found statistically significant decreases in combined IL and NIL counts, total lesion counts, and comedones in patients randomly assigned to doxycycline [122]. The fourth study also evaluated subantimicrobial doses of doxycycline (20 mg b.i.d.) and found noninferior efficacy compared with conventional dosing (100 mg daily) with respect to IL reduction after 3 months in patients with moderate acne [124]. These patients, however, were not followed to investigate the period of time before their next breakout, which deems this study of limited clinical significance.

Other evidence located included a series of nonrandomized studies in 420 individuals with moderate to severe acne. In a

nonrandomized controlled study of 152 patients matched for age, sex, site of involvement, and severity, those maintained on erythromycin, 1 g daily, and 5% benzoyl peroxide showed a significantly greater response in comparison with those receiving 0.5 g and 5% benzoyl peroxide. The improvements in acne grade at 6 months were 35% and 79% in men and 59% and 79% in women. The relapse rates within 1 year were also significantly lower in the high-dose group: 31% versus 60% in women and 82% versus 39% in men. A similar group of 296 patients did not show higher rates of gastrointestinal side effects at the higher dose [239]. Individuals with severe acne, acne of the trunk, and high SERs responded less well to combined treatment with 5% benzoyl peroxide and erythromycin 250 mg twice daily over 6 months [239].

There are also reports in the literature that higher daily doses of tetracycline [256] and oxytetracycline [230] are more effective in patients with severe acne or acne that is recalcitrant to standard therapy. The results of these studies are questionable, however, as both have serious methodological flaws and used concomitant topical therapy. A cohort of 80 patients with nodulocystic and conglobate acne who had not responded to standard antibiotic doses showed improvement with 1.5–3.0 g tetracycline [257]. A second similar cohort of 31 patients with severe acne or acne resistant to standard-dose antibiotics received up to 3.5 g with concomitant topicals, and 27 of the patients showed great improvement. Fifteen individuals suffered adverse events and two had to discontinue therapy because of raised serum creatinine phosphokinase, emphasizing the need for ongoing renal and hepatic monitoring. The onset of improvement ranged from 1 to 6 months. Flare occurred in nine patients on reduced dose, despite the use of topicals [256].

A prospective case series of 68 patients with moderate to “cystic” acne, in whom the dose was titrated according to the response, found that in a period of up to 2.5 years, 51 of the 58 patients who improved required only 250 mg tetracycline daily [250]. Increased severity of acne was an indicator for higher dose and nonresponse. In 10 cases, tetracycline had no effect, regardless of dose.

### For how long should antibiotic therapy be continued?

This question was not addressed in either of the systematic reviews, and no specific RCT evidence was located. The literature contains a number of recommendations, few of which are backed by hard evidence. The consensus of opinion is that although the effects of antibiotics on ILs are visible after a few days, a minimum of 3 weeks is required before any improvement can be categorically stated [114,252], and therapy should therefore be continued for a minimum of 3 months, and 6 months for maximum benefit [1]. As antibiotics do not expel existing comedones, the effect on these lesions only becomes evident after a few months of continual use; it takes approximately 8 weeks for a microcomedo to develop into a visible lesion. Relapse occurs in nearly half of the patients up to 8 weeks after stopping therapy [258], necessitating additional courses [259]. In patients who relapse immediately, the antibiotic used should be rotated every 6 months [260]. Two RCTs that included intermediate assessments showed that improvement continued beyond 4–6 weeks to 3 months [110,129].

An observational cohort study of 543 patients with moderate acne who were treated with erythromycin, 1 g/day, combined with 5% benzoyl peroxide suggested that the median percentage improvement at 6 months was 78% (interquartile range 67–90%); 408 of 492 individuals showed an over 50% reduction in acne grade; 247 of 279 who continued with benzoyl peroxide alone maintained

improvement; 174 individuals who continued with combination for a further 6 months showed no additional benefit, but this group also included a subgroup of responders, nonresponders, and those switched to alternative antibiotics. Therapy was continued in 31 patients who had not shown 50% improvement within the 6-month period; the percentage improvement was greater in the 29 individuals treated with minocycline.

### What is the role of oral isotretinoin in the treatment of severe acne?

Severe, treatment-resistant acne is frequently treated with oral isotretinoin. Although its complete mechanism of action has yet to be elucidated, oral isotretinoin has been shown to decrease sebum excretion, keratinization, inflammation, and follicular colonization by *P. acnes* and other organisms, such as *Pityrosporum* spp.

#### Efficacy

The efficacy of systemic isotretinoin in the treatment of severe, cystic acne is well demonstrated. The AHRQ systematic review identified 11 RCTs which evaluated the outcomes of isotretinoin therapy [261–271]. One trial [271] used SER as its only measure of drug efficacy, and included no results regarding clinical outcome (number of lesions, summated cyst diameter, severity of disease, etc.). It was therefore excluded from the RCTs listed (Web Table 19.12). Three other trials [272–274] were found through searching PubMed. At least nine of the 13 RCTs were investigator blinded, with three of the remaining four not indicating any blinding protocol.

Five RCTs [262,263,268,270,273] compared isotretinoin therapy with placebo or other traditional, first-line therapies (etretinate, tetracycline, dapsone, minocycline). In all cases, isotretinoin was found to be a more effective therapy than its comparators. One study concluded that 0.5 mg/kg per day isotretinoin therapy for 16 weeks was significantly more effective than placebo, with a 97% overall decrease in number of cystic lesions at 41 months posttreatment [268]. Goldstein *et al.* [262] reported 1.0 mg/kg per day isotretinoin to be significantly more effective than 1.0 mg/kg per day etretinate after an 8-week course of therapy and at an 8-week posttreatment visit ( $P < 0.05$ ). Tetracycline performed equally well as isotretinoin by the end of a 16-week course of therapy in one RCT. However, at a 24-week visit (8-weeks posttreatment), isotretinoin therapy demonstrated a statistically significant decrease in the number of cystic lesions when compared with tetracycline therapy (85% overall reduction in number of lesions,  $P < 0.02$ ) [263]. Isotretinoin therapy was significantly more effective than dapsone therapy, as demonstrated by one 16-week RCT [270]. Isotretinoin therapy resulted in significantly fewer lesions on both face and trunk at 20, 28, and 36 weeks (4, 12, and 16 weeks posttreatment respectively). Isotretinoin therapy also achieved a better clinical result over minocycline in one 20-week RCT [273].

A recent RCT demonstrated that the addition of topical treatments, such as 1% clindamycin twice daily and 0.1% adapalene daily, to oral isotretinoin did not provide any additional efficacy in terms of clinical reduction in NILs and ILs in patients with severe nodulocystic acne [275].

Eleven RCTs compared various isotretinoin dosage regimens ranging from 0.1 mg/kg per day to 2.0 mg/kg per day [261,264, 267,269,272,274,276–278]. All doses studied resulted in a significantly decreased number of lesions. However, no dose-related clinical response could be detected among the doses tested. Only one trial [269] reported (somewhat anecdotally) that higher doses of

oral isotretinoin resulted in better clinical outcomes. However, no statistics were available to substantiate this claim. A recent RCT suggests that conventional daily dosing (1 mg/kg per day) for the first 8 weeks of treatment followed by alternating regimens (1 mg/kg every other day) or low-dose regimens (20 mg every other day) for another 8 weeks yields a similar reduction in total lesions compared with 16 weeks of daily dosing in patients with severe acne [276]. In addition, this “tapered” approach minimized the common side effects of oral isotretinoin.

Two similar RCTs support alternate dosing for patients with moderate acne. One study argued that both conventional (0.5–0.7 mg/kg per day) and low-dose (0.25–0.4 mg/kg per day) regimens have similar efficacy for patients with moderate acne [277], while another demonstrated that intermittent therapy has similar efficacy to conventional therapy in moderate acne [278]. Both of these studies, however, were not adequately powered to evaluate equivalence. Further investigation is needed to support alternative dosing for patients with moderate disease.

Several studies have also demonstrated significantly decreased SER [261,262,264,266,268,270,274], free fatty acid excretion [261], and bacterial [261,270] and yeast colonization with isotretinoin therapy. SER was shown to be significantly reduced in both a dose-dependent [264,266,267,272,274] and dose independent manner in several studies, but was also found to resume near-normal levels following termination of treatment at a rate that was inversely proportional to isotretinoin dosage [264,266,268,270]. In other words, higher doses of isotretinoin resulted in a more prolonged decrease in SER. One study reported a significant decrease in SER at 16 weeks posttreatment with 1.0 mg/kg per day ( $P < 0.0025$ ) [266]. The mechanism of decreased SER seems to be related to sebaceous gland atrophy, which begins to occur after 3 weeks of isotretinoin treatment [268,279,280]. Decreases in bacterial and yeast colonization were also noted in several studies [261,270]. One study noted a statistically significant, dose-independent decrease in anaerobic bacteria colonization after 16 weeks of treatment, but not of aerobic bacteria [261]. The same study also noted statistically significant, dose-independent decreases in *Pityrosporum* spp. at 16 weeks. Another study noted a statistically significant decrease in both aerobic and anaerobic bacteria colonization during treatment with isotretinoin [270]. It is hypothesized that the decreases in colonization are an indirect result of alterations in the microenvironment necessary for the survival of skin-surface microorganisms, rather than a direct antimicrobial effect [261,281,282].

Six RCTs included posttreatment evaluation in order to determine rates of long-term disease remission/relapse. Several studies noted a further decrease in acne severity during the posttreatment follow-up period [262–265,268,270]. Furthermore, one study noted that the degree of disease remission was significantly greater in patients who had been treated with higher doses of oral isotretinoin [265]. In one 20-week study, 40% of patients treated with 0.1 mg/kg per day needed to be retreated, while only 10% of patients who had been treated with 1.0 mg/kg per day needed retreatment [265]. Another study reported similar findings [268].

### Adverse effects

The teratogenic effect of isotretinoin is well documented [283]. None of the trials reported pregnancies, births, or birth defects. Most trials either excluded women with childbearing potential from the study or advised women to take adequate contraceptive measures.

Significant side effects of oral isotretinoin therapy were identified in all RCTs. In general, side effects were limited to the muco-

cutaneous membranes. Side effects were generally more severe with higher doses of isotretinoin therapy and generally resolved within 1 month of discontinuance of therapy. The most frequently cited side effects included cheilitis, xerosis, pruritus, facial dermatitis, epistaxis, and desquamation [261–270,272,273]. Hair loss [262,264,265,267,273], arthralgia [265,266,268,269,272], and decreased appetite [265,268,273] were reported in a small percentage of patients. Most patients chose to live with side effects in order to benefit from the effect of isotretinoin on the clearance of their acne. Very few patients discontinued therapy because it was unmanageable.

Several studies have investigated the relationship between depression/suicidal behavior and isotretinoin-treated acne patients [284–293]. However, these studies have not identified an association between depression/suicidal tendencies and isotretinoin therapy. Despite these negative findings, a consensus regarding the potential association has not been reached, primarily due to limitations (sample size, study design, etc.) of the studies. An important retrospective study from Sweden recently evaluated the potential link between oral isotretinoin, depression, and suicide. The study found that the risk of suicide attempts compared with the standard incidence of attempted suicide steadily increased 1 year prior to therapy, peaked at 6 months of therapy, and returned to baseline 3 years posttherapy. The rise in suicide attempts 6 months after treatment initiation cannot be solely linked to therapy because the risk was already gradually rising from 1 year previous [294].

Additionally, oral isotretinoin was found to cause a steady increase in serum triglyceride levels during treatment in several studies [263,269,272,273]. However, triglyceride levels were shown to decrease to normal levels after drug cessation [263–268,272,273]. Other laboratory findings included slight, transient elevations in serum protein [263,264,272], serum glutamic oxaloacetic transaminase [263,264,266,269,272], serum glutamic pyruvic transaminase [263,267,268], alkaline phosphatase [267], and serum cholesterol [269,270]. These elevations resolved either during or soon after cessation of treatment.

### Comment

In an effort to eliminate fetal exposure to isotretinoin in the USA, all isotretinoin distributors, distributing pharmacies, prescribers, and patients (both male and female) are required to register with the iPledge Program [295]. Female patients are required to report that two forms of contraception are being used simultaneously to their physician, as well as the results of a monthly pregnancy test. These protocols must be followed for 1 month prior to and 1 month following isotretinoin therapy. Male patients are not required to report contraceptive use, however, as there is not yet any evidence that isotretinoin therapy in males can cause teratogenic effects in fetuses. The iPledge Program was initiated in March 2006, and its efficacy in reducing fetal exposure to isotretinoin has yet to be fully determined [296].

### Implications for practice

Owing to the myriad potential side effects of oral isotretinoin, its use should ideally be reserved for the treatment of severe, recalcitrant acne. The many potential side effects of oral isotretinoin, including teratogenicity, mucocutaneous complaints, elevated lipids, elevated serum protein or liver transaminases, arthralgia, decreased appetite, and the possibility of depression with suicidal ideation, require close monitoring of the patient at regular intervals. The current recommendation suggests that the general practitioner

assesses for disturbances in mental health for 1 year after therapy cessation. Patient education should also be an integral part of isotretinoin therapy.

The teratogenicity of oral isotretinoin requires that extra care should be taken when prescribing the drug to female patients and demands that adequate methods of contraception should be insisted upon in order to prevent birth defects. Laboratory monitoring should include pregnancy screening for female patients, and periodic serum triglyceride, cholesterol, and liver function tests may be indicated for all patients during isotretinoin therapy.

Lastly, more prolonged course of therapy (16–20 weeks) with a relatively low dose of isotretinoin ( $\leq 1$  mg/kg per day) may provide an optimal balance between long term outcomes and side effects.

### Key points

- Antibacterial washes should be considered in the first-line management of mild acne and in the maintenance of individuals who have improved following other therapy. They should not be used routinely in conjunction with other therapies. There is no evidence to support the use of abrasives, which may further irritate already sensitized skin. Syndet bars are less irritant than soap for cleansing.
- Topical retinoids can be used in both noninflammatory and inflammatory acne and in conjunction with oral and topical antibiotics. The evidence suggests that adapalene is less irritant than other retinoids, though newer retinoid delivery systems produce less irritation.
- Azelaic acid is effective in mild to moderate acne and may be less irritant than topical retinoids, but has a slower onset of response.
- Benzoyl peroxide is an effective treatment in mild to moderate acne, but causes an initial sensitization that may persist in some individuals. Higher strength benzoyl peroxide is in general no more effective than at lower strength, but is associated with more irritation.
- Antibiotics are more effective against ILs than against NILs. There is no evidence to support a difference in efficacy between any of the agents, either oral or topical, although topical therapies are more cost effective.
- There is no good-quality evidence to support recommendations about either the dose or duration of antibiotic therapy; further research is needed.
- Benzoyl peroxide appears to have similar activity to antibiotics against ILs and greater activity against NILs, but causes local irritation. The evidence suggests that combined use of antibiotics with retinoids is more active than either agent alone, and whilst benzoyl peroxide combinations are more effective than antibiotics alone, the data against benzoyl peroxide alone are equivocal.
- Given concerns about the development of resistance, further research is urgently required to assess the efficacy of antibiotics relative to other agents and to provide data for an appropriate assessment of the risks and benefits associated with their continued use. Benzoyl peroxide should be used intermittently during extended antibiotic therapy to eliminate any resistant strains.
- Switching from an antibiotic regimen to a combination topical retinoid and benzoyl peroxide reduces antibiotic resistance.
- Oral isotretinoin should be reserved for severe, treatment resistant acne due to potentially serious adverse side effects, including teratogenicity.
- Patients on oral isotretinoin should be monitored for changes in lipids and liver enzymes.
- Patients requiring oral isotretinoin should be screened for depression before treatment is initiated and monitored for depression and suicidal ideation during therapy.

## CHAPTER 20

# Papulopustular rosacea

Alfredo Rebora and Francesco Drago

Clinica Dermatologica, Department of Health, University of Genoa, Genoa, Italy

### Background

#### Definition

Papulopustular rosacea is a stage of rosacea in which papulopustules appear on the nose and cheeks, more rarely on the forehead and chin, and exceptionally on the neck and other body areas, such as the bare skull or the back. In some cases, papules show a granulomatous infiltrate, which is clinically identified from the yellowish color of the lesions and their duration (Figure 20.1). Lymphedematous rosacea is more rare and is characterized by chronic and persistent edema in the periocular and perinasal areas. The edema persists even when inflammation has abated and is probably linked to inflammatory damage to the regional lymphatic vessels. A hyperacute episode, in which most of the face is invaded by papulopustules (facial pyoderma), has also been described as rosacea fulminans.

Typically, rosacea is a multistage disease. The stages are the flushing stage, or transitory congestive redness; the erythrosis stage, of persistent telangiectatic redness; the papulopustular stage; and the phyma stage. Only a minority of patients with the first two stages of the disease progress to the papulopustular stage and fewer to the phyma stage.

Although ocular symptoms are recorded in as many as 20.8% of cases, the introduction of a stage named “ocular rosacea” is not acceptable. Ocular rosacea goes through most of the stages mentioned above, including a congestive stage (blepharo-conjunctivitis) and a papulopustular stage (sties and chalazas).

#### Incidence/prevalence

Rosacea is a very common disease. In the USA, it is the fifth most frequently diagnosed skin condition after acne, atopic dermatitis, psoriasis, and actinic keratoses. It affects 10% of the general population in Sweden.

A recent study in the UK revealed that the overall incidence of rosacea is 1.65 per 1000 persons/year, with a definite prevalence of women (61.5%). In 80% of cases, rosacea is diagnosed after the age of 30 years [1]. However, this depends on the stage in which the condition is diagnosed. In 1979 in Italy, the flushing stage was in fact found to occur already in the second decade of life and eryth-

rosis at the mean age of 34 years. Phymas develop later (mean age 66 years).

#### Etiology/risk

The etiopathogenesis of papulopustular rosacea is controversial. Heredity is important. It has been shown that 20% of the children with steroid rosacea had at least one close blood relative with rosacea. Fair complexion, blond hair, and green/blue eyes are characteristics of patients with rosacea. Southern, darker complexions, therefore, have a lower incidence. In fact, only about 0.1% of colored people are affected by rosacea, as reported by an old American observation.

Also unclear is why a patient proceeds from stages that are mainly functional to stages that are inflammatory. Both cell-mediated and humoral arms of immunity are certainly involved. Antibodies directed against collagen VII, the pericapillary elastotic tissue, and the *Demodex folliculorum* mites have been detected. However, the production of antibodies may be a secondary event, or the elastotic tissue and *D. folliculorum* may simply represent structures on which antibodies accumulate spontaneously (“beach effect”). In addition, *Helicobacter pylori*, a Gram-negative bacterium, may play a role. Opinions diverge on its association with rosacea, but drugs that eradicate *H. pylori* were used to treat papulopustular rosacea efficaciously long before the discovery of the bacterium.

Recently, attention has been paid to cathelicidin processing, which would be disturbed in rosacea resulting in the production of peptide fragments responsible for inflammation and telangiectases. Cathelicidin is strongly increased in rosacea lesional skin, and the injection into the skin of mice of the peptide fragments found in skin of rosacea patients leads to a rosacea-like disease. In particular, the role of cathelicidin LL-37 has been studied. Its expression in human keratinocytes is regulated by the vitamin D pathway, and this could explain why rosacea occurs in the sun-exposed sites. Other external stimuli, like infections, injuries, and disruption of the permeability barrier, have been found to trigger the induction of cathelicidin synthesis in keratinocytes. Doxycycline efficacy has been explained by its capacity to prevent cathelicidin activation [2,3].

**Figure 20.1** A patient with rosacea (a) before and (b) after treatment. (Figures provided by Andrew Herxheimer.)

### Prognosis

No long-term prognostic studies are available.

### Aims

The aims of treatment are to suppress the symptoms and to maintain such suppression over time.

### Outcomes

The following outcome measures are used: state of lesions over time; use of routine treatments; duration of remission; patient satisfaction; disease-related quality of life; adverse effects of treatments, and clinical activity scores.

### Methods

One Cochrane review was published in 2005 and included 29 studies, one systematic review, and one partial review [4]. A new Cochrane review was published in 2011 and included 58 studies [5]. None of the patient-reported outcome assessment tools met the recommended criteria based on the quality “checklist.” In six of the studies the self-assessments were made by way of questionnaires of unsupported validity, and in general the quality of the evidence was considered only low to moderate [6].

## Questions

### What are the effects of systemic treatments?

#### Tetracycline

##### Efficacy

In the Cochrane review on cutaneous and ocular rosacea [4], data pooled from three studies of oral tetracyclines versus placebo, including 152 participants, showed that tetracycline was effective (odds ratio [OR], 6.06; 95% confidence interval [CI], 2.96–12.42).

The systematic review of ocular rosacea examined 11 papers, only three of which were randomized controlled trials (RCTs). The proportion of patients with improvement ranged from 20% to 100%. It was concluded that there is a moderate benefit with oxytetracycline, whilst the efficacy of tetracyclines and doxycycline could not be established [7].

##### Drawbacks

Diarrhea at 750 mg/day was reported in one study and in 25% of cases treated with 40 mg/day [7].

##### Comment

In one RCT, a very minor placebo effect contrasted with all the other trials, in which there was a very marked placebo effect.

#### Doxycycline

Doxycycline is perhaps the most popular medication for papulopustular rosacea, but the Cochrane review did not identify any RCTs on doxycycline at traditional doses.

##### Efficacy

In one controlled clinical trial (CCT), 17 patients received doxycycline 200 mg/day for 4 weeks and then 100 mg/day for another month. The lesions cleared in 90% of patients in 8 weeks. Comparison with clarithromycin favored the latter [8]. An anecdotal report of two cases stated that 100 mg/day for 9 weeks and 50 mg/day for 1 month were sufficient to clear the lesions [9].

In more recent years, doxycycline has been used at a lower dose (40 mg/day), allegedly providing an anti-inflammatory activity. It proved more effective than topical metronidazole [10,11] or placebo [12] in RCTs. A physician-based assessment revealed no statistical difference in efficacy between the 40 and 100 mg doses [13]. In a recent large, open-label, multicenter, community-based study,

modified-release doxycycline capsules (30 mg immediate-release and 10 mg delayed-release beads) were used once daily for up to 12 weeks in 1421 patients with papulopustular rosacea. Significant improvements in severity rating and erythema were observed in more than 70% of patients [14].

### **Drawbacks**

Side effects (primarily mild or moderate gastrointestinal events) were complained of in about 10% of cases treated with 40 mg/day [14].

### **Comment**

Doxycycline is a photosensitizing agent in fewer than 1% of patients, but this characteristic should not be neglected in rosacea patients, who are usually fairly skinned. Bacterial resistance to subantimicrobial-dose doxycycline might arise after such low-dose treatment. In addition, although well designed, the recent RCTs on 40 mg doxycycline did not address the patients' views [15].

### **Ampicillin**

Ampicillin is rarely used.

### **Efficacy**

In the only RCT, 17 patients were treated with ampicillin 750 mg/day for 6 weeks. There was a 55% improvement in the lesions. When the results were assessed by a scoring system, tetracycline and ampicillin proved significantly better than placebo; tetracycline was better than ampicillin, but the difference did not quite reach the 5% significance level [16].

### **Drawbacks**

Two patients developed diarrhea within a few days and withdrew from the study.

### **Comment**

The benefit/harm ratio appears to be low.

### **Clarithromycin**

No systematic reviews and no RCTs were found.

### **Efficacy**

In the only CCT, 23 patients received clarithromycin 500 mg/day for 1 month and then 250 mg/day for a further month. Ninety percent of the lesions cleared in 8 weeks; the comparison with doxycycline was in favor of clarithromycin [8].

### **Drawbacks**

Clarithromycin was significantly better tolerated than doxycycline.

### **Comment**

Clarithromycin is almost four times more expensive than doxycycline.

### **Azithromycin**

There are no systematic reviews or RCTs.

### **Efficacy**

One randomized open clinical trial found azithromycin as equally effective as doxycycline, but the standard deviations were large and the data were skewed [17]. An uncontrolled study reported that

clearing occurred in 9 of 10 patients treated with azithromycin 500 mg/day for 4 weeks followed by 250 mg/day for 3 months [18]. Another uncontrolled study reported that 10 adults treated with azithromycin (250 mg three times/week) had moderate or marked improvement within 4 weeks [19]. Another open-labeled study included 18 patients who received azithromycin for 12 weeks, in decreasing doses. In the 14 patients who completed the study, the total scores significantly decreased by 75%, and the improvement continued during the month after treatment [20].

### **Drawbacks**

Nausea in one patient resolved without the treatment having to be interrupted.

### **Comment**

A once-daily pulse-dosing regimen may improve compliance.

### **Metronidazole**

Oral metronidazole appears to be highly effective in papulopustular rosacea.

### **Efficacy**

In the first of two RCTs, 29 patients received metronidazole 400 mg/day for 6 weeks. The benefit was significantly superior to placebo [21]. In the second trial, 40 patients received 400 mg/day for 12 weeks. The improvement was similar to that obtained with oxytetracycline [22]. An uncontrolled trial treated 59 patients with 500 mg/day for no more than 6 months, obtaining 90% success rate [23]. Further trials have been published in German [24].

### **Drawbacks**

Headache and furred tongue have been noted occasionally.

### **Comment**

Metronidazole is reported as having a disulfiram-like effect. This must be a very rare side effect, as in my (AR) large personal experience I have never come across it.

### **Eradication of *Helicobacter pylori***

It is still a matter of controversy whether *H. pylori* is involved in the pathogenesis of rosacea. However, eradication of *H. pylori* results in clearing papulopustular rosacea.

### **Efficacy**

Only one RCT was found, in which 44 patients were treated with omeprazole 40 mg/day plus clarithromycin 1500 mg/day for 2 weeks. Skin lesions cleared in almost all patients, but there were no differences from the untreated controls [25]. In one CCT, 37 patients received omeprazole 40 mg/day for 1 month, plus clarithromycin 100 mg/day, plus metronidazole 2000 mg/day for 2 weeks. At the 12th week, 76% of the patients experienced improvement, compared with no improvement in the 26 untreated patients [26]. In another CCT, 53 patients received omeprazole 20 mg/day, clarithromycin 1 g/day, and metronidazole 1 g/day for 1 week. Ninety-six percent cleared in 2–4 weeks [27]. In a controlled non-randomized study, 13 patients improved on bismuth 1200 mg/day, amoxicillin 500 mg/day, and metronidazole 1.5 g/day [28].

### **Drawbacks**

Surprisingly, no information is provided regarding any side effects of such a complex therapy.

**Comment**

The Cochrane systematic review regarded the data reported for clarithromycin and omeprazole as unusable [5]. The results, however, are homogeneously in favor of the efficacy of the eradication of *H. pylori*, with the exception of the RCT. It is very difficult to believe, however, that the placebo-treated patients improved as much as those who received the eradication therapy. It has to be noted, however, that the RCT did not use metronidazole [25].

**Isotretinoin**

Isotretinoin is a drug for very severe cases, such as pyoderma faciale.

**Efficacy**

No systematic reviews were found, but there was one RCT in which 20 patients received isotretinoin 10 mg/day for 4 months. They improved significantly [29]. In an uncontrolled study, 22 patients received isotretinoin 10 mg/day for 4 months. They improved by 50% in 9 weeks [30]. Two anecdotal reports described clearance in 3–6 months [31,32].

**Drawbacks**

Most patients experienced dry lips and facial xerosis, and 25% a mild to moderate increase in serum triglyceride levels.

**Comment**

Long-term side effects have not been reported.

**Octreotide****Efficacy**

In an anecdotal observation, the lesions cleared in three of four patients [33].

**Zinc sulfate**

We found two RCTs dealing with zinc sulfate.

**Efficacy**

In one RCT [34], zinc sulfate 100 mg three times a day improved significantly facial rosacea in 19 patients. Improvement started directly after the first month of therapy. After shifting to placebo treatment, rosacea relapsed gradually in the fifth month, but its severity remained significantly lower than before therapy. In the second RCT [35], 220 mg of zinc sulfate was given twice a day for 3 months to 44 patients with moderately severe rosacea. Rosacea improved in both treated and placebo groups. No differences were noted.

**Drawbacks**

Mild gastric upset was noted in 12% of cases of the first RCT.

**Comment**

Additional studies are needed.

**What are the effects of topical drugs?**

Topical drugs are less likely to cause systemic adverse effects than systemically administered drugs, and compliance may be better. It should be noted, however, that the rosacea skin is extremely reactive to external agents, including cosmetics, and that skin mites, like *D. folliculorum*, are lipophilic organisms that may be fed by oily medications. According to the Cochrane study [6], most of the

studies with topical treatments other than antibiotics are at high risk of bias and had skewed or unusable data.

The drug that has been most widely tested is metronidazole.

**Metronidazole**

Metronidazole, formulated as either a 1% cream or a 0.75% gel, has proved effective in papulopustular rosacea [36].

**Efficacy**

The Cochrane review [4] found that topical metronidazole is more effective than placebo. Although most of the studies did not specifically address participants' satisfaction with treatment and were largely physician assessed, the lesion counts were in fact reduced. Most studies used 0.75% metronidazole applied twice a day. Different formulations, such as gel, cream, and lotion, are deemed to be equivalent. The treatment period varied from 8 to 9 weeks in most trials, but was 6 months in one study. The Cochrane review documented improvement over placebo in both "self-assessment by the patient" (three studies; OR, 5.96; 95% CI, 2.95–12.06) and physician global evaluation (three studies; OR, 7.01; 95% CI, 3.56–13.81). The data on continuous outcome measures, such as the number of lesions, could not be pooled because of the lack of relevant information, such as standard deviation.

However, these data supported the positive treatment effect. In an RCT, 88 patients, previously treated successfully with oral tetracycline and topical metronidazole, were treated with either 0.76% metronidazole gel or a vehicle. Relapses after 6 months of treatment were significantly fewer (23%) with metronidazole than with the vehicle (42%) [37].

Two studies compared metronidazole with oral tetracyclines [38,39]. Neither study could demonstrate a statistical difference between the drugs analyzed. However, the studies were too small ( $n = 25$  and  $n = 26$ ) to document a clinically significant difference. Two studies compared topical metronidazole with topical azelaic acid. One study ( $n = 251$ ) [40] was not able to document any difference (OR, 1.32; 95% CI, 0.79–2.21) in patient self-assessment, but both the physician assessment and count of inflammatory lesions were in favor of azelaic acid (inflammatory lesions 12.9 vs 10.7;  $P = 0.003$ ). The other study ( $n = 40$ ) [41] involved a within-patient comparison, and again found that azelaic acid was slightly superior to metronidazole. The clinical significance of the difference documented is difficult to define. In one study in which topical metronidazole was compared with permethrin ( $n = 63$ ) [42], no difference was documented in the erythema score or papule count, but there was a reduced number of pustular lesions in the permethrin group.

**Drawbacks**

Side effects occurred in 2–4% of patients and included dryness, burning, and stinging. One paper reported that both the metronidazole gel and its excipient seemed to be poorly tolerated [43].

**Comment**

The majority of papers were RCTs (some even multicenter), mostly comparing the drug with a vehicle, but were sponsored by manufacturers.

**Azelaic acid**

Azelaic acid has been found to be effective in rosacea [44]. The Cochrane review found four RCTs comparing azelaic acid with placebo and one RCT comparing the drug with topical metronidazole.

**Efficacy**

Both 15% and 20% azelaic acid concentrations have been used in placebo-controlled RCTs, and the treatment period ranged from 12 to 13 weeks. It was estimated that about five patients had to be treated to obtain one experiencing complete remission or marked improvement (number needed to treat, 5; 95% CI, 4–7) [40]. Two RCTs reported comparisons with topical metronidazole (see above) [40,41]. Azelaic acid 15% gel proved to be more irritant than metronidazole 0.75% gel in a series of 33 patients [45].

**Drawbacks**

Burning and stinging have been noted.

**Comment**

The quality of the studies was generally poor [44].

**Sulfur**

Sulfur appears to be effective in rosacea. Two RCTs were found.

**Efficacy**

In the first RCT [46], 20 patients were treated for 1 month with a 10% sulfur cream plus placebo tablets and compared with 20 patients treated with lymecycline 150 mg/day plus placebo cream. Ninety-two percent of the lesions cleared with both treatments. In the second study, a total of 94 patients were treated with a combination of 10% sodium sulfacetamide and 5% sulfur in a lotion for 8 weeks. Inflammatory lesions decreased by 78%, in comparison with 36% in the vehicle group [47].

**Drawbacks**

Reactions at the application site decreased in frequency over time.

**Permethrin****Efficacy**

An RCT has been carried out, including 63 patients randomly assigned to permethrin 5% gel, metronidazole 0.75% gel, or placebo. Permethrin was as effective as metronidazole gel and significantly superior to placebo (see above) [42].

**Tretinoin/isotretinoin**

Isotretinoin may be effective in rosacea.

**Efficacy**

In one small RCT, six patients were treated with 0.025% tretinoin cream for 16 weeks. Lesion counts decreased by 42%. No additional benefit was noted if the patients were also treated with oral isotretinoin [29]. In an uncontrolled small trial, four patients were treated with 0.2% isotretinoin cream for 16 days. Inflammatory lesions responded better than noninflammatory lesions [48].

**Drawbacks**

No side effects were noted.

**Comment**

It is well known that isotretinoin irritates normal skin, but surprisingly it does not irritate the sensitive rosacea skin.

**Clindamycin**

Two RCT have been published. In the first one, 43 patients were randomly assigned to treatment with either 1% clindamycin phosphate lotion for 12 weeks or tetracycline 1000 mg for 3 weeks and then 500 mg for 9 weeks. All inflammatory lesions decreased signifi-

cantly (by about 60%) in the clindamycin arm, while only papules and nodules decreased significantly in the tetracycline arm [49].

In the second RCT, 70 patients with moderate to severe papulopustular rosacea were treated with a combination topical clindamycin phosphate 1.2% and tretinoin 0.025% for 3 months. The combination may improve the telangiectatic component of rosacea rather than papulopustules [50].

**Drawbacks**

Facial scaling was noted in the second RCT, though it did not lead to discontinuation.

**Benzoyl peroxide****Efficacy**

In the only CCT, patients were treated with 5% benzoyl peroxide acetone gel for 1 month and with 10% gel for a further month. Benzoyl peroxide was superior to placebo [51].

**Drawbacks**

Twenty-three percent of the patients treated with benzoyl peroxide dropped out of the study.

**Calcineurin inhibitors**

In one RCT [52], topical 1% pimecrolimus was found not to be better than the vehicle. In another open-label study [53], 26 patients were treated with 1% pimecrolimus cream for 1 month. Rosacea clinical scores were significantly reduced from  $9.65 \pm 1.79$  at baseline to  $7.27 \pm 2.11$  at the end of treatment ( $P < 0.05$ ). The side effects were mostly transient local irritations. In a randomized, open-label study, 48 patients were treated with either pimecrolimus 1% cream or metronidazole 1% cream for 12 weeks [54]. Both treatments were very effective without any significant differences. There is also an anecdotal report of a successful treatment of granulomatous rosacea [55]. Tacrolimus has been tried only in telangiectatic rosacea with good results in 60% after 6 weeks [56].

**Comment**

Rosacea-like and granulomatous dermatitis has been reported to occur in patients with the continuous use of topical calcineurin inhibitors [57,58].

**Laser and/or light-based treatments**

They were directed essentially on erythematotelangiectatic rosacea and cannot be analyzed here. "Acne rosacea" was less responsive [59].

**Key points**

- Only a few RCTs have been conducted on systemic agents. In particular, no RCTs have tested doxycycline, clarithromycin, or azithromycin.
- Many RCTs have been performed with topical drugs. In particular, metronidazole has been extensively and thoroughly studied.
- Almost all of the drugs examined were found to be effective, and this is surprising given the profound chemical diversity of the drugs used and the poor explanation provided for their activity.
- Side effects were surprisingly minimal, even for drugs such as tretinoin and benzoyl peroxide which are well-known irritants.
- In many studies, a high rate of response to placebos was observed.
- The large majority of RCTs have been directly supported by the manufacturer. The obvious conflict of interest cannot be neglected in evaluating the results.

## CHAPTER 21

# Perioral dermatitis

Vincenzo Bettoli, Stefania Zauli, and Annarosa Virgili

Department of Clinical and Experimental Medicine, Section of Dermatology, University of Ferrara, Arcispedale S. Anna, Ferrara, Italy

## Background

### Definition

Perioral dermatitis is a common inflammatory and chronic facial dermatitis symmetrically involving the area delimited by the alae of the nose and the chin. It can also involve periorbital and perinasal areas. For this reason, perioral dermatitis is also known as periorificial dermatitis.

It is characterized by an eruption of 1–2 mm erythematous papules, papulopustules, or papulovesicles (Figure 21.1). Acneiform eruption may also be present. Frequently the eruption occurs with diffuse erythema and scaling and often spares a narrow zone around the vermillion border.

An associated sensation of burning is common, while itching is not usually present [1,2].

### Incidence/prevalence

The exact incidence and prevalence are unknown. Perioral dermatitis in 90% of the cases affects women in the 16–45 age group. The incidence in men is increasing. The condition is seldom seen in children, particularly from age 7 months to 13 years [1,2].

### Etiology

The etiology of perioral dermatitis is unknown. The possible causative factors include infection, such as *Candida* or *Demodex*, use of potent topical steroids, cosmetics, fluoride toothpastes, physical factors (UV, heat, wind), hormonal or emotional factors, the use of oral contraceptives, and the presence of gastrointestinal disturbance [1].

### Prognosis

Following discontinuation of the offending etiologic factor, and with the appropriate treatment, perioral dermatitis generally regresses in a few weeks. Perioral dermatitis is therefore associated with an excellent prognosis.

### Aims of treatment

When treating patients with perioral dermatitis, physicians aim to achieve clinical clearance in a time as short as possible and prevent recurrence, while minimizing the adverse effects of treatment.

## Outcomes

The standard outcomes of treatment include clinical clearance, recurrence rates, and adverse effects of treatment.

To assess clinical severity of perioral dermatitis, a score, the perioral dermatitis severity index (PODSI), was developed in 2005. This index represents the sum of individual scores for erythema, papules and scaling using a scale from 0 (none) to 3 (severe), including intermediate values (0.5, 1.5, and 2.5) and resulting in a total score from 0 to 9 [3].

## Methods of search

To identify studies on the treatment of perioral dermatitis, Medline (until 2012) was checked for publications in English. Since only a few randomized controlled trials (RCTs) were identified, publications including case series were included. Evidence was graded using the level of evidence scale system reported by Hall and Reichenberg [2]. All evidence found in the literature is presented.

## Questions

### What are the effects of “zero therapy”?

#### Level of evidence: A

“Zero therapy” means avoiding the use of cosmetics and corticosteroids.

The subjects who made up the control group of four randomized clinical trials and who were treated with an oral placebo or a vehicle cream were counseled to avoid using topical corticosteroids and cosmetics. Most of these patients cleared within 2–3 months, with significant improvement generally seen in the first 4 weeks [4–7].

#### Comment

In four studies, perioral dermatitis, in patients of the control groups that did not receive an active treatment, resolved within 2–3 months after topical corticosteroids and cosmetic suspension.

### What are the effects of metronidazole?

#### Metronidazole 1% cream/metronidazole 0.75% gel

#### Level of evidence: A

We found no studies comparing metronidazole 1% cream with placebo.

**Figure 21.1** A patient with perioral dermatitis.

There is only one prospective, double-blind, double-dummy, multicenter RCT that compares metronidazole 1% cream with oral tetracycline in the treatment of perioral dermatitis [8].

As far as metronidazole 0.75% gel is concerned, no systematic reviews or RCTs have been found.

#### **Efficacy**

The multicenter RCT was conducted in 109 patients randomly assigned to receive either 1% metronidazole cream plus placebo tablets twice daily, or placebo cream and tetracycline tablets (250 mg twice daily) [8].

In the metronidazole group, the median number of papules was reduced to 33% of the original number after 4 weeks and to 8% after 8 weeks. The median number of papule reductions in patients treated with tetracycline was reduced to 4% after 4 weeks, and 0% at 8 weeks. Tetracycline was significantly more effective in reducing the number of papules after 4 and 8 weeks of treatment ( $P < 0.01$ ). No significant differences were noted in any of the other categories evaluated, which included erythema and patient and physician assessments.

#### **Drawbacks**

Seven patients out of 54 in the metronidazole group and nine out of 54 patients in the tetracycline group complained of adverse effects, the most common of which included abdominal discomfort, pruritus, and dryness of the face.

#### **Level of evidence: C**

A retrospective study evaluated the efficacy of topical metronidazole used alone or in combination with other medications such as oral erythromycin in 41 children or adolescents from 6 months to 18 years of age [9].

In this group of patients, perioral dermatitis was reported to last from 1 to 24 weeks (7 weeks on average). In only one patient did the facial rash persist. In contrast to patients who received no treat-

ment or other treatments such as topical calcineurin inhibitors, sulfacetamide, hydrocortisone, and antifungal agents, those patients treated with topical metronidazole, oral erythromycin, or both were associated with absence of lesions at the follow-up visits. No adverse events were reported.

Moreover, in a retrospective study on 15 patients affected by demodicosis, skin lesions rapidly resolved after systemic metronidazole and/or 0.75% gel. In five patients the condition manifested as a perioral dermatitis-like rash [10].

#### **Level of evidence: D**

A case series including seven children using metronidazole 1% cream twice daily showed slow but significant improvement after 4–6 weeks and resolution after 3–6 months [11].

#### **Level of evidence: E**

Eleven out of 17 cases of perioral dermatitis in children between the ages of 9 months and 9 years were treated with monotherapy consisting of metronidazole gel 0.75% either once or twice daily. The remaining patients were given combination therapy of metronidazole gel with topical corticosteroids or erythromycin (topical or oral). All patients improved within 8 weeks of therapy. Fourteen patients who were followed up remained lesion-free for up to 16 months. No adverse reactions were reported [12,13].

#### **Comment**

Only one RCT comparing the efficacy of metronidazole 1% cream with that of oral tetracycline is available. It shows that tetracycline is more effective than metronidazole 1% cream in reducing the number of the papules. Other available data are related to case series and retrospective studies in children or adolescents. In particular, no studies on adults with perioral dermatitis using metronidazole 0.75% gel were found.

Patients improve with metronidazole, but there are no data to quantify the entity and the rapidity of improvement in comparison with placebo.

### **What are the effects of oral tetracyclines?**

#### **Oral tetracyclines**

##### **Level of evidence: A**

Three randomized clinical trials and many cases series have studied the efficacy of oral tetracyclines, as reported in a recent review [2] of perioral dermatitis therapy [4,5,8,14].

#### **Efficacy**

Data show that the results with tetracycline 250–500 mg orally twice daily for 20–60 days are superior to oral placebo and to metronidazole 1% cream twice daily and either better or equal to topical erythromycin. Most of the papules resolve within the first month of therapy, and complete resolution is achieved in about 2 months [4,5,8].

In only one trial with 50 patients was the treatment with oral tetracycline found to be no more efficacious than “zero therapy” [8].

Weber, in a series of about 700 patients found that, in 2% of the patients who failed to respond to topical erythromycin ointment, oral tetracycline could effectively bring resolution of papules in 3–5 weeks [14].

#### **Drawbacks**

No adverse events were reported.

**Comment**

These three RCTs confirm that tetracycline is an effective first-line treatment for perioral dermatitis and that it is effective also in those who failed other previous treatments.

**Level of evidence: D**

Only low-level evidence and cases series support the use of minocycline, doxycycline, and oxytetracycline [2].

None of the reports were placebo controlled, and many used multiple oral and topical agents in combination. For this reason, it is very difficult to compare the results of different cases.

Furthermore, with the lack of high-quality evidence available, it is difficult to determine the efficacy of these tetracyclines in the treatment of perioral dermatitis.

**What are the effects of topical antibiotics?****Topical tetracycline****Level of evidence: C**

The effects of topical tetracycline were evaluated in the treatment of perioral dermatitis. As the source of this topical preparation was not disclosed, the dose, potency, and efficacy of this type of tetracycline preparation must be questioned.

**Efficacy**

A case series of 30 patients (26 females, 4 males) with clinically typical perioral dermatitis has been reported [15]. Patients were asked to apply topical tetracycline twice daily to all affected areas after gently washing the face. No other treatment was allowed. Twenty-four patients (80%) experienced complete clearing of their condition in 5–28 days; three patients (10%) were at least 50% clear within 28 days; and three patients (10%) discontinued the medication. All patients whose condition cleared were able to maintain clearing with the topical product used on an as-needed basis.

**Drawbacks**

Two patients discontinued therapy due to stinging, and one patient discontinued because of worsening of the dermatitis.

**Comment**

We found no RCTs on the treatment of perioral dermatitis with topical tetracycline.

Based on this case series, topical tetracycline twice daily for 1–4 weeks results in improvement or “clearance” in most of the cases within 28 days.

**Topical erythromycin****Level of evidence: A**

Cases series and a single randomized placebo-controlled trial support the use of topical erythromycin for perioral dermatitis.

**Efficacy**

In the single randomized placebo-controlled trial, 33 patients were treated with topical erythromycin 2% emulsion twice daily, 35 with oral tetracycline, and 33 with placebo. Topical erythromycin was shown to be significantly better than placebo in reducing papules, but at day 20 tetracycline was shown to be superior ( $P = 0.07$ ). Average time to papules clearance was 7 weeks in the topical erythromycin group [5].

In a cases series of 665 patients, all papules disappeared in 79% within 3–5 weeks of treatment with erythromycin 2% ointment [14].

Six patients in a case series were treated with 1.5% erythromycin topical solution twice daily in combination with hydrocortisone valerate cream [16]. Topical 1.5% erythromycin was effective in the treatment of perioral dermatitis, with a mean treatment duration of 4.5 weeks.

**Drawbacks**

Fourteen patients referred to an unbearable burning [14].

**Comment**

One RCT found that erythromycin 2% ointment twice daily for 4–8 weeks results in clearance of papules within 3–5 weeks, showing a better efficacy than placebo [5,14]. Total clearance of erythema may need several more weeks.

**What are the effects of nonfluorinated corticosteroids?****Hydrocortisone butyrate****Level of evidence: D**

Insufficient evidence has been found on the effects of nonfluorinated corticosteroids in patients with perioral dermatitis. One study, a split-face randomized trial of hydrocortisone butyrate versus 1% hydrocortisone alcohol cream in the treatment of rosacea, atopic dermatitis, and perioral dermatitis, is available.

**Efficacy**

In the double-blind, split-face, randomized trial, patients with perioral dermatitis (eight patients), rosacea (18 patients), or atopic dermatitis (two patients) were randomly treated on one side of their face with hydrocortisone alcohol 1% cream and the other side with 0.1% hydrocortisone butyrate [17]. Only patients with severe disease were selected. The participants were instructed to apply the creams twice daily to the appropriate side of the face. Six of the eight patients with perioral dermatitis also received oxytetracycline 250 mg twice daily. The patients were reexamined weekly by the same physician until more improvement was noted on one side of the face in comparison with the opposite side. If no difference was detected, treatment continued for up to 3 months. In addition, the patients were reexamined 1 week after treatment was withdrawn to determine whether any rebound occurred. Two patients with perioral dermatitis achieved better results with hydrocortisone alcohol 1% cream (mean duration of therapy 3.5 weeks, range 3–4 weeks), four patients improved more with hydrocortisone butyrate (mean duration: 3–5 weeks, range 2–5 weeks), and two patients found both treatments equally effective.

**Drawbacks**

Two patients with perioral dermatitis showed a moderate rebound of the eruption after withdrawal of topical treatment, in each case on the hydroxybutyrate-treated side of the face.

**Comment**

In view of the study design and the small numbers of patients, it is difficult to draw conclusions.

**Other treatment modalities****Photodynamic therapy with 5-aminolevulinic acid****Level of evidence: C**

No placebo-controlled RCTs were found. The only evidence for the treatment of perioral dermatitis with 5-aminolevulinic acid (ALA)–photodynamic therapy (PDT) was one prospective, split-face trial

performed without randomization (in most cases, the side with the highest number of lesions was treated with ALA-PDT) [18]. The concentration of the comparator, clindamycin gel applied once daily, was not disclosed. In addition, the results were reported in terms of the per-protocol population ( $n = 14$ ) instead of the intention-to-treat population ( $n = 21$ ).

### Efficacy

In a split-face study including 21 patients (19 women and 2 men), perioral dermatitis was treated with unoccluded ALA followed by treatment with 410 nm blue light for 8 min on one side of the face and with topical clindamycin phosphate gel applied daily on the other side [17]. The patients had to have at least three facial lesions (as identified by clinical observation) on each side of the face. Patients who completed the study received an average of three weekly PDTs (range 1–4) each over 1 month. The responses were considered complete if no lesion was seen at the treatment site. Patient-graded satisfaction was reported using a five-point scale (where 5 was complete satisfaction) [18].

Fourteen patients (66.7%) completed the study, all of whom received four PDTs to achieve complete or nearly complete clearance by either treatment modality. Seven patients did not complete the study owing to skin photosensitivity irritation brought on by a failure to avoid sun exposure for the recommended 48 h after treatment. The mean post-treatment lesion counts – 1.4 for ALA-PDT and 2.3 for clindamycin gel – did not differ significantly ( $P = 0.1140$ ). However, the mean lesion counts after treatment were significantly less than the mean lesion count at baseline for both ALA-PDT ( $P < 0.0001$ ) and clindamycin gel ( $P = 0.0001$ ). The sides treated with ALA-PDT achieved a significantly better mean clearance ( $P = 0.0227$ ) in comparison with the clindamycin side (clearance of 92.1% with ALA-PDT and clearance of 80.9% with clindamycin). In nine of the 14 patients, the greater level of clearance was on the ALA-PDT side. The mean patient satisfaction level for the side treated with ALA-PDT was 4.4; the level of satisfaction for the clindamycin gel side was not reported [18].

### Drawbacks

Mild postinflammatory hyperpigmentation occurred in three patients in the study. In addition, skin photosensitivity irritation reactions can occur in those who do not avoid sun exposure for 48 h after treatment [18].

### Comment

In the absence of large-scale, well-designed RCTs, it is difficult to fully assess the impact of ALA-PDT in the treatment of perioral dermatitis. In addition, this seems to be the only published trial incorporating topical clindamycin into a treatment regimen for

perioral dermatitis; but again, it is difficult to draw conclusions concerning this treatment modality owing to the small number of patients and the overall study design.

### Azelaic acid

#### Level of evidence: C

There are no placebo-controlled RCTs involving azelaic acid in the treatment of perioral dermatitis. Only two open clinical trials investigating the efficacy and tolerability of 20% azelaic acid cream in the treatment of perioral dermatitis in a total of 20 patients, 10 adults and 10 children, were found [19,20].

### Efficacy

Ten adult patients with perioral dermatitis were treated with 20% azelaic acid cream applied twice daily (overall duration of use not specified). All patients responded to treatment within 2–3 weeks, with clearing of all lesions within 2–6 weeks. There were no reported recurrences of the disease after 4–10 months of follow-up [19].

Ten children (from 3 to 12 years of age) applied 20% azelaic acid cream twice daily until complete resolution of the perioral dermatitis, which occurred after 4–8 weeks. No recurrence was observed in a follow-up period of 2–8 months [20].

### Drawbacks

Two of the 10 adult patients reported erythema, itching, and dryness of the face. These were observed mainly in the initial 2 weeks of treatment [19].

Six of the 10 children complained of burning, erythema, or scaling immediately after topical application, above all during the first 2 weeks of treatment [20].

### Comment

There is a definite need for placebo-controlled and comparative RCTs before any comment can be made on the effectiveness of azelaic acid in the treatment of perioral dermatitis.

### Topical pimecrolimus

#### Level of evidence: A

Two randomized, double-blind vehicle-controlled studies, one with 124 patients and one with 40 patients, have been published [6,7].

### Efficacy

Data regarding the efficacy of a 4-week treatment with pimecrolimus cream 1% are reported in the Table 21.1.

In the study including 40 patients, 20 of them received pimecrolimus cream 1% and 20 a vehicle cream. The PODSI reduced from  $4.5 \pm 1.3$  to  $1.6 \pm 1.8$  in the pimecrolimus group and from  $4.6 \pm 1.1$  to  $2.6 \pm 1.5$  in the placebo group. The time of response

**Table 21.1** The results of RCTs evaluating the use of pimecrolimus cream 1% in perioral dermatitis.

	No. patients	PODSI				Time of response (weeks) (decrease PODSI $\geq 50\%$ )		Patients with recurrence (increase PODSI $\geq 50\%$ )	
		Pimecrolimus		Vehicle		Pimecrolimus	Vehicle	Pimecrolimus	Vehicle
		Before	After	Before	After				
Oppel <i>et al.</i> [7]	40	4.5 $\pm$ 1.3	1.6 $\pm$ 1.8	4.6 $\pm$ 1.1	2.6 $\pm$ 1.5	1	4	Not assessed	
Schwarz <i>et al.</i> [6]	124	5.2	2.1	5.2	2.4	1 (40% patients) 4 (65% patients)	1 (11%) 4 (60%)	10	6

was more rapid in the pimecrolimus group. In this study, follow-up after treatment lasted 4 weeks [7]. The rate of relapse was not evaluated.

In the study including 124 patients, 60 were treated with pimecrolimus cream 1% and 64 with a vehicle cream. A total of 112 patients completed the treatment phase. The PODSI reduced from 5.2 to 2.1 in the pimecrolimus group and from 5.2 to 2.4 in the placebo group. Forty percent of patients in the pimecrolimus group and 11% of patients in the placebo group improved at least 50% in only 1 week. Follow-up lasted 8 weeks after treatment suspension. Perioral dermatitis relapsed in 10 patients treated with pimecrolimus and in six patients treated with placebo. Maximal benefit was seen in patients with a history of topical corticosteroid use [6].

### Drawbacks

A total of nine patients treated with pimecrolimus cream 1% and seven patients in the placebo group complained of adverse events, mainly erythema, burning sensation, and itching. Three patients treated with pimecrolimus and one with vehicle developed herpes simplex [6,7].

### Comment

These studies show that pimecrolimus cream 1% applied twice a day for 4 weeks works better than the vehicle. It leads to a more rapid improvement of perioral dermatitis, already seen after 1 week. Pimecrolimus cream seems to be more effective in patients with a history of use of topical corticosteroids.

## Acknowledgments

We would like to thank Aditya K. Gupta, author of this chapter in the previous edition.

### Key points

- Six RCTs have been conducted to determine appropriate therapies for the treatment of perioral dermatitis.
- It appears that tetracycline has been used as a standard treatment in adults with some efficacy, as reported in three RCTs.
- Topical 1% metronidazole cream has been shown to be effective in one RCT.
- Recently, topical 1% pimecrolimus cream has been shown to be effective in two RCTs.
- Most of the available evidence for these and other treatments comes from case series.

# Hand eczema

Wietske A. Christoffers, Marie-Louise Anna Schuttelaar, and Pieter-Jan Coenraads

Department of Dermatology, University of Groningen, University Medical Center Groningen, Groningen, Netherlands

## Introduction

### Definition

The term “hand eczema” implies an inflammation of the skin (dermatitis) that is generally confined to the hands, but sometimes the feet are involved as well. Clinically, the condition is characterized by signs of redness, vesicles (tiny blisters), papules, edema, scaling, fissures (cracks), erosions, and hyperkeratosis (callus-like thickening), all of which may be present at different points in time (Figure 22.1). Itch, sometimes severe, is a common feature. Fissures and blisters might be painful and impair manual work.

**Figure 22.1** Hand eczema: redness, erosions, and tiny blisters, accompanied by severe itching.

Microscopically, the disease is characterized by spongiosis with varying degrees of acanthosis, and a superficial perivascular infiltrate of lymphocytes and histiocytes.

### Incidence and prevalence

Hand eczema is considered a common condition, with a point prevalence of 1–5% among adults in the general population, and a 1-year prevalence of up to 10%, depending on whether the disease definition includes more pronounced or mild cases [1]. The prevalence may be higher in some countries. Hand eczema is twice as common in women as in men, with the highest prevalence in young women. The reasons for this sex difference are unknown, although

greater exposure of women to wet work is probably contributory. Reliable data on the incidence are scarce, and are mainly confined to estimates in particular occupational groups. The incidence of notified work-related cases is between 0.7 and 1.5 cases per 1000 workers per year with much higher annual incidences among high-risk occupations, such as bakers and hairdressers [2].

### Etiology

The etiology is multifactorial. Contact irritants are the commonest external causes. Hand eczema caused by such irritants, or mild toxic agents, is known as irritant contact dermatitis. Water is a contact irritant, and thus an external causal or contributing factor. Causal factors that are less common than irritants are contact allergens. Hand eczema caused by skin contact with allergens is called allergic contact dermatitis. Ingested allergens (for example, nickel) may also provoke hand eczema. Being atopic (to produce immunoglobulin E (IgE) antibodies in response to ordinary exposures to allergens, usually proteins and, as a consequence, the tendency to develop asthma, rhinoconjunctivitis, or eczema) is a major predisposing factor responsible for hand eczema. A combination of the above-mentioned factors appears to play a role in many patients.

Hand eczema can be classified by etiology: irritant contact dermatitis, allergic contact dermatitis, atopic hand eczema, protein contact dermatitis, or a combination of these types. A morphological classification of hand eczema is: vesicular hand eczema (dyshidrotic, pompholyx), hyperkeratotic hand eczema, fingertip dermatitis (pulpitis), nummular hand eczema, interdigital eczema, and dry fissured hand eczema.

### Prognosis

When there is a single, easily avoidable contact allergic factor, the prognosis is good. Several studies, however, have suggested that hand eczema tends to run a long-lasting and chronic relapsing course, probably because of the multifactorial origin.

### Diagnostic tests

The diagnosis is mainly based on history and clinical signs; there are no standardized diagnostic criteria. Patients are patch-tested to detect or rule out a contact allergy. In addition, prick tests or determination of specific IgE are performed to detect atopy, and skin scrapings are performed to rule out a mycotic infection. In the majority of cases, no relevant contact allergy can be detected. Specific prick tests of specific IgE are of additional value only in

very special cases (contact urticarial reactions that can become eczematous; protein contact dermatitis).

Differential diagnostic psoriasis, mycosis, lichen planus, scabies, granuloma annulare, herpes simplex, and artefacts might be considered.

## Treatment

The treatment of hand eczema is aimed at reducing clinical symptoms (including the disabling itch), preventing relapses, and reducing the burden of disease by allowing the resumption of everyday manual tasks. The outcome of the treatment can be assessed in different ways. Relevant outcome parameters include:

- the percentage of patients reporting a good/excellent response;
- the percentage of patients with an investigator-reported good/excellent response;
- reduction in severity (patient-rated and physician-rated scoring systems);
- dose reduction;
- time until relapse.

## Objectives

In daily practice, we often ask ourselves what treatment would be best for the patient with hand eczema who is sitting in front of us. This usually involves a comparison between different treatment modalities. Against this background, we formulated 14 clinically relevant questions.

Because of the tendency of hand eczema to develop a chronic or relapsing course, all of the questions are concerned with chronic hand eczema. In the context of this chapter, chronicity can arbitrarily be defined as a duration of more than 6 months.

## Methods of search

Controlled trials dating back to 1977 were located by searching the Skin Group Specialized Register, Cochrane Central Register of Controlled Trials (CENTRAL), PubMed, and Embase in February 2013 for original articles in English, French, German, or Dutch. Uncontrolled trials were discarded, unless systematic reviews and controlled trials were lacking on a specific subject. Also, papers studying different dermatoses and not specifically stating the results for the patients with hand eczema were ignored. The questions were formulated before the search, and only papers pertaining to these questions were included.

## Questions

Because of the tendency of hand eczema to develop a chronic or relapsing course, all of the questions considered below deal with chronic hand eczema, arbitrarily defined as a duration of more than 6 months. Prescription of topical corticosteroids is at present the most common treatment; therefore, it is the major comparator in the questions listed below.

- In adults with chronic hand eczema, do topical coal-tar preparations lead to a better patient-rated or physician-rated reduction in symptom scores than topical corticosteroids?
- In adults with hyperkeratotic hand eczema, does dithranol lead to an improvement in patient-rated and physician-rated symptom scores and longer remission periods after clearance in comparison with topical corticosteroids?
- In adults with chronic hand eczema, do short bursts of potent topical corticosteroids (class 3 or 4) lead to better patient-rated or physician-rated symptom scores than continuous mild (class 1 or 2) topical steroids?

- In adults with chronic hand eczema, are oral immunosuppressive agents (ciclosporin, methotrexate, mycophenolate mofetil, azathioprine) better in maintaining a long-term (more than 6 months) reduction of patient-rated or physician-rated symptom scores than topical corticosteroids?
- Is the treatment of chronic hand eczema with local psoralen-ultraviolet A (PUVA) or ultraviolet B (UVB) irradiation better in reducing patient-rated and physician-rated symptom scores than topical corticosteroids?
- In adults with chronic hand eczema, does treatment with PUVA irradiation (oral or topical psoralen) lead to a better reduction in patient-rated and physician-rated symptom scores and remission periods than UVB irradiation?
- In adults with chronic hand eczema, is oral treatment with retinoids better in terms of patient-rated and physician-rated symptom scores than topical corticosteroids?
- Is the treatment of chronic hand eczema with calcineurin inhibitors better in reducing patient-rated and physician-rated symptom scores than topical corticosteroids?
- In adults with dyshidrotic hand eczema, does iontophoresis lead to an improvement in patient-rated and physician-rated symptom scores in comparison with topical steroids or UVB/PUVA irradiation?
- In adults with relapsing vesicular hand eczema based on contact allergy to nickel, does dietary intervention or oral therapy with chelating agents lead to an improvement in patient-rated and physician-rated symptom scores in comparison with topical corticosteroids?
- Does the daily application of a bland emollient lead to dose reduction and/or frequency reduction of topical corticosteroids in adults with chronic hand eczema?
- In adults with chronic clinically active hand eczema, do protective or occlusive gloves or barrier creams lead to better patient-rated or physician-rated symptom scores than topical steroids?
- Does the addition of a topical antibacterial agent to topical corticosteroids result in better patient-rated or physician-rated symptom scores than topical corticosteroids alone?
- In patients with chronic hand eczema, is an educational intervention program effective for secondary and tertiary prevention on hand eczema compared with limited education as usual?

## In adults with chronic hand eczema, do topical coal-tar preparations lead to a better patient-rated or physician-rated reduction in symptom scores than topical corticosteroids?

One clinical trial was identified on the effect of coal tar. Additional trials may be found in the older literature (pre-1977).

### Efficacy

No systematic reviews were found.

### Coal tar

In a self-controlled, randomized study, the efficacy of coal tar paste with zinc oxide paste was compared with betamethasone valerate 0.1% in 19 patients with a within-patient design. Coal tar gave significant improvement compared with baseline, but no significant difference was observed between the treatments [3].

### Drawbacks

Six participants dropped out because they experienced problems with wearing hand gloves (problems were not specified). One

participant dropped out due to pompholyx as a result of contact allergy to 5% coal tar.

### Comment

Small number of participants ( $n = 19$ ) with relatively high drop-out rate ( $n = 7$ ). The results are listed as overall mean scores and no exact data are given.

### Implications for clinical practice

The scientific-based evidence for coal tar treatment is scarce; however, trials may be found in the earlier literature (pre-1977). Contrary to belief, coal tar is not associated with an increased risk of cancer [4].

### In adults with hyperkeratotic hand eczema, does dithranol lead to an improvement in patient-rated and physician-rated symptom scores and longer remission periods after clearance in comparison with topical corticosteroids?

No systematic reviews were found, and no trials (controlled or uncontrolled) of dithranol for any type of hand eczema were identified. Trials may be found in the earlier literature (pre-1977).

### In adults with chronic hand eczema, do short bursts of potent topical corticosteroids (class 3 or 4) lead to better patient-rated or physician-rated symptom scores than continuous mild to moderate (class 1 or 2) topical steroids?

We found no studies comparing the effect of short bursts of strong (class 3 or 4) topical corticosteroids (for example, twice weekly, or at weekends only) with continuous application of milder (class 1 or 2) topical corticosteroids. One randomized controlled trial (RCT) compared thrice-weekly application versus weekend application of the same steroid, with limited evidence that the thrice-weekly application was better.

### Efficacy

No systematic reviews were found.

### Thrice-weekly versus weekend application

There is limited evidence of a preferential effect of thrice-weekly application of mometasone in a parallel group RCT with 106 participants in a 30-week maintenance phase (i.e., after induction of remission) [5].

### Once-daily versus twice-daily application

In a controlled trial with once-daily halcinonide 0.1% versus twice-daily betamethasone dipropionate 0.05% both showed good efficacy in 53 participants during 4 weeks [6]. In half of the patients, once-daily halcinonide 0.1% was superior.

### Two different concentrations

One left–right RCT of 2 weeks' duration comparing different concentrations of the same corticosteroid applied twice daily detected no difference in 46 participants [2].

### Class 2 versus class 3 corticosteroids

One RCT compared short-term (3 weeks) application of fluprednide acetate 0.1% cream (class 2) with betamethasone valerate 0.1% cream (class 3), both in a once-daily regimen in 76 participants [7]. There were no differences in the time to onset of effect or clinical efficacy.

### Class 2 versus class 4 corticosteroids

In a double-blind left–right RCT with 61 participants, more patients remained free of relapses with clobetasol propionate than with fluprednide acetate [8]. In addition, the time to relapse was longer with clobetasol propionate. Treatment initially and in case of recurrence was twice daily; in the maintenance phase, the application was twice weekly. The side effects were comparable between the two groups.

### Drawbacks

Mild skin atrophy was reported in two studies [5,8].

### Comment

With the exception of the study on thrice-weekly versus weekend application, all of the studies were of short duration. The primary outcome was not always clearly stated, and some studies included patients in relapse. None of the studies investigated tachyphylaxis or atrophy. Earlier reports (pre-1977) may provide some insight into this issue.

### Implications for clinical practice

The appropriate choice of an optimal topical steroid treatment schedule cannot be derived from the current literature on hand eczema trials. Evidence from studies on other eczematous diseases may have to be considered.

### In adults with chronic hand eczema, are oral immunosuppressive agents (cyclosporin, methotrexate, mycophenolate mofetil, azathioprine) better in maintaining a long-term (more than 6 months) reduction of patient-rated or physician-rated symptom scores than topical corticosteroids?

One RCT was identified, showing that cyclosporin was effective, but not significantly better in terms of clinical signs or quality of life. One RCT concluded that azathioprine is an effective adjunctive treatment option. We identified no RCTs studying other oral immunosuppressive agents.

### Efficacy

No systematic review was found.

### Cyclosporin versus topical betamethasone

An RCT compared cyclosporin with betamethasone dipropionate 0.05% twice daily in 41 participants [9]. The study had three phases, none of which showed a comparative advantage in terms of clinical signs, global assessment, or cumulative relapse rate. The first treatment phase was 6 weeks; the second and third amounted to 30 weeks.

### Methotrexate

We identified no controlled trials.

An uncontrolled case study showed low-dose methotrexate to be effective in five patients with recalcitrant palmoplantar pompholyx [10].

### Mycophenolate mofetil and azathioprine

We identified no controlled trials.

### Azathioprine as adjunctive

One RCT compared the additional value of azathioprine to topical clobetasol propionate 0.05% cream with topical clobetasol

propionate monotherapy in 108 patients with chronic hand eczema for 24 weeks [11]. This study reported a significant better improvement with regard to hand eczema severity index score and itch in the azathioprine group.

### Drawbacks

Paresthesia (“tingling”), dizziness, facial edema, and increase in serum creatinine were reported during ciclosporin use. Surprisingly, no side effects were reported for azathioprine.

### Comment

The comparator in the ciclosporin studies was a relatively strong corticosteroid.

### Implications for clinical practice

Ciclosporin may be useful for achieving short-term control, but cannot be recommended for maintenance therapy. Long-term side effects such as blood dyscrasia, renal failure, increased blood pressure, and skin malignancies are of major concerns. Choices regarding systemic treatment of hand eczema cannot be derived from the current literature on hand eczema trials.

### Is the treatment of chronic hand eczema with local psoralen+ultraviolet A or ultraviolet B irradiation better in reducing patient-rated and physician-rated symptom scores than topical corticosteroids?

We identified no trials explicitly comparing PUVA or UVB therapy with topical corticosteroids; only one RCT had ordinary topical treatment with emollients as the comparator. Several controlled trials were identified that compared the efficacy of PUVA, UVB, or UVA1 therapy with a control group or using a left–right design. There is insufficient evidence that PUVA or UVB therapy is more effective than conventional topical corticosteroid therapy.

### Efficacy

No systematic reviews were found.

### Topical psoralen+ultraviolet A

In a double-blind randomized within-patient trial of 15 patients with chronically relapsing vesicular hand eczema, topical PUVA and UVA treatment showed improvement of the severity score over the 8-week treatment period, but no statistical difference between the treated hands at any stage [12].

In a controlled clinical trial (CCT) with a left–right design, topical cream PUVA was compared with UVA1 [13]. The study comprised 27 patients with bilateral dyshidrotic hand eczema. Almost all patients showed a good response to both treatments, with a reduction of physician-rated scores of 50%. There were no statistically significant differences between the left and right hands.

In an observer-blinded, left–right design, there was little difference between topical 8-methoxypsoralen (8-MOP) bath PUVA and topical 8-MOP lotion PUVA therapy in 24 patients with chronic hand or foot eczema; there was greater than 80% clearing with both modalities [14]. After 1 month, the most successful treatment was continued on both sides until the lesions cleared; there were no differences in the length of the relapse-free period.

An open-label RCT with 158 participants showed that oral PUVA at home was equally effective as topical bath PUVA in the hospital [15]. In addition, it appeared to result in lower costs and less time off work.

In a within-participant RCT with 15 participants, the effectiveness of middle-dose UVA1 irradiation was compared with topical cream PUVA therapy [16]. Treatment was given thrice weekly during a period of 5 weeks. Both groups improved, but there was no significant difference between the groups.

An observer-blinded RCT in 29 participants showed no significant difference between topical and oral psoralen, although oral PUVA might be preferred in hyperkeratotic hand eczema [17].

### Ultraviolet A1

In a double-blind RCT with 28 patients with dyshidrotic hand eczema, five-times weekly irradiation with UVA1 was compared with placebo [18]. After 1 week of treatment, a significant difference was seen between the two groups, with greater efficacy for UVA1.

### Ultraviolet B

Eighteen patients with chronic hand eczema resistant to potent topical corticosteroids were randomly divided into three treatment groups: UVB of the hands only, placebo irradiation, and whole-body UVB irradiation [19]. Local UVB irradiation of the hands was significantly better than placebo; whole-body UVB irradiation with additional irradiation of the hands was significantly better than continuing the local treatment alone (not specified), according to a simple clinical grading (cleared, improved, unchanged/worse). A 3-month follow-up period demonstrated fast relapse of the hand eczema.

In an RCT with 48 patients with occupational hand eczema, UVB at home 5 days a week for 8 weeks was compared with nonspecific topical treatment [20]. Physician-rated scores and transepidermal water loss improved in both groups, although the improvement did not reach statistical significance for most parameters.

### Drawbacks

Ultraviolet therapy can cause side effects such as burning episodes, subacute eczema, patchy hypopigmentation, and acute exacerbation of eczema. It may also induce skin cancer as a long-term effect.

### Comment

In some studies, patients continued their topical medication or emollients. There are no studies comparing PUVA, UVA1, or UVB therapy with the conventional topical corticosteroid therapy. There is also no evidence that ultraviolet therapy is the most effective for hand eczema (see the next question).

### Implications for clinical practice

PUVA and UVB are effective; UVA1 also appears to be effective. The choice of these treatment options is guided by considerations other than proven clinical superiority over other modalities.

### In adults with chronic hand eczema, does treatment with psoralen+ultraviolet A irradiation (oral or topical psoralen) lead to a better reduction in patient-rated and physician-rated symptom scores and remission periods than ultraviolet B irradiation?

We identified two RCTs on oral PUVA and two CCTs on oral/topical PUVA. The controlled trial on topical bath PUVA

demonstrated no comparative advantage, whereas the RCT on oral PUVA showed an effect in favor of PUVA.

### Efficacy

No systematic review was found.

### Topical bath psoralen+ultraviolet A versus ultraviolet B

A 6-week left–right design CCT including 13 patients showed that, although effective, topical bath PUVA was not better than UVB [21].

### Oral psoralen+ultraviolet A versus ultraviolet B

An RCT showed an effect in favor of oral PUVA in a 3-month study of 35 patients. In this study, only one hand was treated, but in most patients the untreated hand also improved [22].

In a 9-week RCT with left–right design, 15 patients were treated with local narrowband UVB or PUVA thrice a week. Both groups showed significant improvement compared with baseline and a local narrowband UVB phototherapy regimen is as effective as PUVA therapy in patients with chronic hand eczema of dry and dyshidrotic types [23].

A CCT comparing UVB used at home with PUVA at the clinic in 26 patients during approximately 10 weeks, showed no comparative advantage [24].

### Drawbacks

Nausea caused by the oral psoralen was reported. Pain, burning, itching, and redness were reported with both therapies, but slightly more from PUVA irradiation.

In both PUVA and UVB, mild xerosis was reported, which responded to emollients.

### Comment

Long-term adverse effects could not be assessed. Improvement of the untreated hand may be the result of compliance with topical emollients. More than 17 uncontrolled studies were identified, claiming a beneficial effect of ultraviolet treatment (PUVA or UVB), but there was no comparator in any of the studies.

### Implications for clinical practice

PUVA or UVB is effective in treating hand eczema. The question of which modality is better remains unsolved.

### In adults with chronic hand eczema, is oral treatment with retinoids better in terms of patient-rated and physician-rated symptom scores than topical corticosteroids?

We identified several trials on the use of retinoids in hand eczema; there were no trials comparing oral retinoids with corticosteroids. Both topical and oral treatment with retinoids appeared to be effective.

### Efficacy

No systematic reviews were found.

### Topical retinoid versus topical corticosteroids

In a symmetrical double-blind nonrandomized study, the efficacy of triamcinolone acetonide 0.1% cream was compared with the

same cream containing, in addition, 0.25% retinoic acid [25]. The study included 18 patients with different types of eczema (12 with atopic dermatitis, four with allergic contact dermatitis, one with nummular eczema, and one with dyshidrosis); the palms and soles were involved in only five patients. The duration of treatment was planned for 2 weeks, with the option of extending the treatment to 3 weeks. No statistically significant differences were observed between the treatments.

An open-label RCT with 55 patients compared bexarotene gel monotherapy (ligand for retinoid X receptors) with the same gel in combination with either mometasone furoate 0.1% ointment or with hydrocortisone acetate 1% ointment [26]. The steroids were applied twice daily, whereas bexarotene gel was applied in an increasing regimen, starting at once every other day up to three times daily, unless adjustment was needed because of irritation. All groups showed a meaningful decrease in physician-rated scores, without significant differences between the groups.

### Oral retinoids

An RCT including 29 patients with hyperkeratotic hand eczema compared once-daily 30 mg acitretin with placebo [27]. A significant improvement in comparison with the placebo group was seen in relation to hyperkeratosis, fissures, and scaling, but not in relation to itch, redness, or vesicles. The improvement occurred in the first 4 weeks, with no additional effect seen in the following 4 weeks.

A multicenter, double-blind RCT assessed the efficacy of three different dosages of 9-*cis*-retinoic acid (alitretinoin) and placebo [28]. The 319 patients were equally randomized over four groups: oral alitretinoin 10 mg/day, 20 mg/day, 40 mg/day, and placebo. Alitretinoin led to a significant and dose-dependent improvement in the physician-rated score.

In a large randomized trial alitretinoin (10 or 30 mg per day for up to 24 weeks) was superior to placebo in 1032 patients with chronic severe hand eczema [29]. Of the patients treated with 30 mg alitretinoin, 40% rated their hand eczema as “clear” or “almost clear” at the end of therapy. In the 10 mg group this was 24% and in the placebo group 15%. In an extended open-label trial, 243 patients received 30 mg alitretinoin and the drugs remained well tolerated for overall treatment durations of up to 48 weeks [30]. In addition, the beneficial effects of alitretinoin over placebo were confirmed in a retreatment trial among a subgroup of 117 patients who had relapsed [31].

### Drawbacks

Topical use of retinoic acid plus corticosteroids is reported to cause significantly more subjective irritation than topical corticosteroids without retinoic acid [25,26].

Side effects of oral acitretin are common and almost all patients experience dry skin (especially the lips). The side effects were dose dependent; the most frequently reported were headache (14%, but this was also reported in the placebo group), mucocutaneous signs as dry lips (5%), and flushing (3%). Clinically insignificant increases in serum triglyceride, cholesterol, and creatinine kinase were reported in several trials on alitretinoin. Central hypothyroidism, with no clinical expression, was observed more rarely. Several papers studied the safety of oral alitretinoin, reporting comparable side effects [32,33].

### Comment

Oral 9-*cis*-retinoic acid appears to be a promising treatment option, but it remains to be demonstrated that this drug is more effective

than conventional topical corticosteroids or UVB/PUVA therapy. In addition, evidence of the efficacy and safety of alitretinoin beyond 48 weeks and of the efficacy in vesicular hand eczema is lacking. A pregnancy prevention program is mandatory for women of fertile age because of the teratogenicity of oral retinoids.

### Implications for clinical practice

Oral retinoids appear to be effective in hand eczema, especially in hyperkeratotic hand eczema. However, as there is no comparison with conventional therapy, it is unclear whether it should be a therapy of first choice.

### Is the treatment of chronic hand eczema with calcineurin inhibitors better in reducing patient-rated and physician-rated symptom scores than topical corticosteroids?

Two RCTs were found that compared the efficacy of topical tacrolimus with mometasone furoate, which appeared to be equivalent and in two RCTs tacrolimus was significantly more effective than vehicle. Two RCTs compared topical pimecrolimus with vehicle cream.

### Efficacy

No systematic reviews were found.

### Tacrolimus

Sixteen patients were included in a left–right RCT comparing topical tacrolimus 0.1% ointment with mometasone furoate 0.1% ointment (a class III corticosteroid) [34]. The treatment period was 4 weeks, with a follow-up period up to 8 weeks. Both treatments led to a statistically significant decrease in clinical severity, with no significant differences between the groups.

In another RCT, topical tacrolimus 0.1% was compared with mometasone furoate in 30 patients for 90 days [35]. Both treatments showed similar therapeutic results.

A randomized pilot study in 32 patients with moderate to severe hand eczema suggested that tacrolimus might prolong the time until relapse compared with vehicle cream during 14 weeks [36].

In an RCT, 28 participants with moderate to severe nickel sulfate-induced allergic hand eczema were treated with 0.1% tacrolimus ointment twice daily versus twice daily vehicle ointment during 14 days. The symptom scores were significantly lower in the tacrolimus group compared with the vehicle group during treatment and 7 days afterwards [37].

### Pimecrolimus

In a multicenter RCT, 294 patients with hand eczema were allocated to up to 3 weeks' treatment with pimecrolimus 1% cream or to vehicle [38]. Twice-daily application of the study creams (evening application under occlusion) was continued until clearance or completion of 3 weeks' treatment. The efficacy of pimecrolimus 1% cream increased over time, while that of the vehicle stagnated after the second week. There were no statistically significant differences between the two groups, unless stratification for palmar involvement was applied; pimecrolimus 1% cream was superior in these patients.

In a multicenter, double-blind, RCT 652 patients were treated for 6 weeks with pimecrolimus 1% or vehicle cream twice daily with overnight occlusion, followed by a 6-week open-label pimecrolimus treatment [39]. There were no significant differences with regard to disease signs; however, pruritus relief was significantly better in the pimecrolimus group.

### Drawbacks

Tacrolimus 0.1% ointment produced stinging upon application; with pimecrolimus 1% cream, however, this was uncommon (0.7% vs 2.1% in the vehicle group) or comparable to the vehicle cream [39].

### Comment

The effect of pimecrolimus 1% cream in comparison with the vehicle might have reached significance if the follow-up period had been longer, as the efficacy of pimecrolimus 1% cream increased over time. Pruritus relief was greater in the pimecrolimus group, but the other studies did not include patient-rated scores.

### Implications for clinical practice

Topical tacrolimus is more effective than vehicles, but is at best equally effective as topical corticosteroids. Pimecrolimus is as effective as vehicles. With the present evidence, calcineurin inhibitors may be used for rotational therapy with topical corticosteroids, with potent corticosteroids for (severe) exacerbations and topical calcineurin inhibitors in the maintenance phase and for mild exacerbations.

### In adults with dyshidrotic hand eczema, does iontophoresis lead to an improvement in patient-rated and physician-rated symptom scores in comparison with topical steroids or ultraviolet B/psoralen+ultraviolet A irradiation?

We identified only one RCT using iontophoresis in patients with dyshidrotic hand eczema, showing a significant improvement on the iontophoresis-treated side in comparison with the untreated side. We found no trials comparing iontophoresis with topical corticosteroids or UVB/PUVA therapy.

### Efficacy

No systematic reviews were found.

### Iontophoresis versus no treatment

In a randomized left–right comparison, the effects of tap-water iontophoresis in addition to steroid-free topical therapy were investigated in 20 patients with dyshidrotic hand eczema [40]. After 3 weeks (20 iontophoresis applications), the parameters “itching” and “vesicle formations” scored significantly better on the iontophoresis-treated side than on the untreated side, but redness and desquamation did not differ significantly.

### Drawbacks

Tap-water iontophoresis was always associated with subjective sensations such as stinging and discrete paresthesia (“tingling”). No severe side effects or possible harmful effects were reported.

### Comment

We found insufficient evidence for the benefit of additional iontophoresis therapy in comparison with conventional corticosteroid or UVB/PUVA therapy.

### Implications for clinical practice

Iontophoresis appears to be harmless, but has not been proved to be effective.

### **In adults with relapsing vesicular hand eczema based on contact allergy to nickel, does dietary intervention or oral therapy with chelating agents lead to an improvement in patient-rated and physician-rated symptom scores in comparison with topical corticosteroids?**

We identified three small RCTs and one CCT. None of the studies compared the intervention with topical corticosteroids. An RCT on triethylenetetramine found no significant improvement of hand eczema. Another RCT, on tetraethylthiuram disulfide (disulfiram), found only very limited evidence in favor of this treatment. One controlled trial found no evidence that a low-nickel diet improves dyshidrotic hand eczema.

#### **Efficacy**

No systematic reviews were found.

#### **Oral therapy with a nickel-chelating compound**

In a multicenter, randomized, double-blind, crossover study, oral treatment with triethylenetetramine 300 mg daily for a 6-week period or placebo were given to 23 nickel-positive patients with chronic hand eczema [41]. No significant improvement occurred in hand eczema on the basis of either the patients' or the doctors' evaluations. The study was terminated prematurely because of literature reports on teratogenicity in rats.

In a double-blind, placebo-controlled RCT, tetraethylthiuram disulfide at a gradually increased dosage was given for at least 6 weeks after the full dosage of 200 mg had been reached [42]. During the treatment period, the hand eczema healed in five of the 11 patients treated with tetraethylthiuram disulfide in comparison with two of 13 in the placebo group (not significant). Using a semi-quantitative scoring system, the results in favor of tetraethylthiuram disulfide were statistically significant for scaling and frequency of flares, but not for the sum of the parameters.

#### **Low-nickel diet**

In a probably nonrandomized trial including 24 patients with dyshidrotic hand eczema caused by nickel, the effects of a low-nickel diet for 3 months (eight patients) were compared with oral disodium cromoglycate for 3 months (nine patients) and with seven patients who did not give consent to the study and did not receive any treatment [43]. All 24 patients were evaluated blindly for itching and number of vesicles. The low-nickel diet did not lead to improvement in these patients, but those treated with disodium cromoglycate improved significantly and had fewer vesicles than the controls and the patients treated by diet.

#### **Combination**

A randomized placebo-controlled trial including 21 patients with chronic vesicular hand eczema with nickel sensitivity stated that the combination of low-nickel diet and short course of oral disulfiram therapy reduced severity of hand eczema statistically after 4 weeks [44].

#### **Drawbacks**

One patient treated with disulfiram had toxic hepatitis after 8 weeks of treatment and two of 30 patients showed signs of hepatic toxicity [42]. Another RCT only noted slight, transient elevation of liver enzymes after 4 weeks [44]. The study on triethylenetetramine was ended prematurely due to a literature report on teratogenicity in

rats [41]. No studies using a low-nickel diet assessed possible harmful effects.

#### **Comment**

None of the trials showed sufficient evidence for the benefit of either a low-nickel diet or a nickel-chelating compound. Only four CTs with small numbers of patients were carried out. On the basis of the harm and possible side effects, oral treatment with a nickel-chelating compound cannot be recommended. None of the trials compared treatments with conventional topical medication (for example, corticosteroids).

#### **Implications for clinical practice**

Given the side effects and the lack of efficacy, oral therapy with a nickel-chelating compound cannot be recommended. There is no evidence that a low-nickel diet improves pompholyx-type hand eczema.

### **Does the daily application of a bland emollient lead to dose reduction and/or frequency reduction of topical corticosteroids in adults with chronic hand eczema?**

One RCT and two uncontrolled studies compared emollients with topical corticosteroids, showing better clinical assessments for emollients, albeit not significant.

#### **Efficacy**

No systematic review was found.

#### **Emollient versus topical corticosteroids**

A double-blind RCT of 2 weeks' duration compared twice-daily application of betamethasone valerate 0.1% with once daily application of betamethasone valerate 0.1% in addition to maintenance therapy with a 5% urea-containing moisturizer in 44 participants. Once-daily treatment combined with emollients showed a better clinical assessment (albeit not statistically significant) compared with twice-daily treatment, especially in the group of patients with a moderate eczema at inclusion [45].

#### **Versus each other**

In one left-right RCT with 30 participants, using patient preference as the outcome parameter, there was limited evidence in favor of Aquacare-HP over Calmurid, both of which contain 10% urea [46].

An RCT in 32 participants confirmed that the frequent application of emollients resulted in better hand eczema scores [47]. However, a superior effect of emollient with ceramides versus a regular petrolatum-based emollient was not demonstrated. This RCT showed that an emollient with ceramides was able to reduce the use of topical corticosteroids.

The beneficial effect of emollients on hand eczema was also seen in a CCT comparing two bland emollients [48]. There was a decrease in transepidermal water loss, as well as an improvement in physician-rated and patient-rated severity scores.

Uncontrolled studies noted a reduction in steroid use in patients treated with a moisturizing cream and in patients treated with a protective foam in 31 and 37 patients [49,50].

#### **Drawbacks**

No major side effects were reported. Burning and worsening of the preexisting hand eczema were reported [46]. Patients were concerned about greasiness of their hands and with staining of objects they handled.

## Comments

Several poor-quality uncontrolled studies were also identified, none of which had steroid dose reduction as the outcome parameter.

## Implications for clinical practice

Despite the widespread use of emollients, there is only little evidence of any steroid-sparing or additive effect in the treatment of hand eczema. In general, there seems to be no harm either, apart from occasional contact allergy against an ingredient.

## In adults with chronic clinically active hand eczema, do protective or occlusive gloves or barrier creams lead to better patient-rated or physician-rated symptom scores than topical steroids?

Information on avoidance of allergens or irritants on a case-by-case basis can be found in the major textbooks on contact dermatitis. The effect of emollients was covered in the previous question. One controlled trial on protective creams was found. We found a few uncontrolled, rather descriptive studies indicating some benefit of gloves and/or barrier creams, and one study used a within-patient left-right design [51,52].

## Efficacy

A number of issues in connection with this question are dealt with in a Cochrane systematic review on irritant hand eczema [53]. They concluded that industrial barrier creams may have a similar role as emollients in the prevention of occupational contact dermatitis; however, there is insufficient evidence that it has a long-term protective effect.

## Barrier creams

In a randomized open trial in 53 patients a barrier-strengthening moisturizer (5% urea) seemed to prolong the disease-free interval in patients with controlled hand eczema compared with no treatment at all (20 vs 2 days) [54].

## Comments

Protective gloves offer protection when manual (wet) tasks are performed; however, prolonged occlusion may be a risk factor for hand eczema [55]. Based on practical experience, supported by an experimental study on the healthy skin of volunteers, a cotton lining or inner glove is recommended [56].

## Implications for clinical practice

Insufficient evidence for long-term protective effect.

## Does the addition of a topical antibacterial agent to topical corticosteroids result in better patient-rated or physician-rated symptom scores than topical corticosteroids alone?

No trials compared the additional effect of topical antibacterial agents with topical corticosteroids alone. Only one RCT comparing betamethasone cream with the addition of either fusidic acid or clioquinol was found, showing a similar effect on clinical severity.

## Efficacy

No systematic reviews were found.

## Addition of fusidic acid or clioquinol to betamethasone

In a multicenter open-label RCT with 120 patients, 4 weeks' twice-daily application of betamethasone 0.1% clioquinol 3% cream was

compared with betamethasone 0.1% fusidic acid 2% cream [57]. The two preparations were equally effective in reducing the observer-rated severity score. However, the combination of betamethasone cream and fusidic acid produced a better bacteriological response.

## Drawbacks

Betamethasone 0.1% fusidic acid 2% cream was considered more cosmetically acceptable than the preparation with clioquinol. The difference was statistically highly significant. Staining of the skin and clothing were the major problems.

## Comment

Staphylococcal superantigens in infected areas elsewhere on the body, although the study protocol allowed them to be treated, might have had an effect on the hands.

## Implications for clinical practice

There were no comparisons of a corticosteroid with a combination of corticosteroid and antibacterial agents. Evidence of an additional effect of antibacterial agents in patients with hand eczema is still lacking.

## In patients with chronic hand eczema, is an educational intervention program effective for secondary and tertiary prevention on hand eczema compared with limited education as usual?

Several RCTs have been conducted on primary prevention, and a systematic review concluded that there is moderate evidence for the effectiveness of primary prevention programs. However, there is low evidence for the effect on improving clinical and self-reported outcomes [58]. We identified two RCTs, one CCT, and one controlled trial on secondary or tertiary prevention.

## Efficacy

A Cochrane review concluded that, although the findings of the review were generally positive, there is insufficient evidence, at present, for the effectiveness of most of the treatments identified for primary prevention of occupation-induced hand eczema in the workplace [53]. No systematic reviews were identified on secondary or tertiary prevention.

## Education programs

An RCT in 255 hospital workers with symptoms of hand eczema showed a beneficial effect of skin care education and individual counseling compared with care as usual (only topical steroids, emollients, and care by general practitioner) after 6 months [59].

In a CCT, 209 geriatric nurses with hand eczema received either care as usual by a dermatologist or a personalized secondary intervention program with education concerning barrier cream and gloves with lectures and hands-on training during four visits. After 3 months the hand eczema significantly improved in the intervention group. More nurses were able to continue their job because of the intervention program compared with those without the program (96 vs 86%) [60].

The Tertiary Individual Prevention study is a multicenter trial with an interdisciplinary, integrated inpatient rehabilitation measure with 3 weeks of inpatient treatment. The 1-year data from 1617 individuals revealed a significant reduction in the severity of occupational skin diseases, the use of topical corticosteroids, and days

of sick leave: 87.4% were able to return to work and to remain in the workforce [61].

### Integrated care

A multicenter RCT with 196 patients received usual care by a dermatologist or integrated care. The integrated care included allergo-dermatological evaluation by a dermatologist, occupational intervention by a clinical occupational physician, and counseling by a specialized nurse on optimizing topical treatment and skin care. After 26 weeks the intervention group scored significantly better on clinical effectiveness, but not on quality of life and days of sick leave [62].

### Drawbacks

Participation in the TIP study was voluntary, but patients were obliged to cooperate with the respective insurance organizations, which makes it difficult to compare this study with other countries.

### Comment

In several studies, no comparator was used. It is difficult to compare different educational programs and to implement in daily practice. Three weeks of inpatient treatment might not be feasible in every setting.

### Implications for clinical practice

Education and counseling seems to improve the effectiveness of hand eczema care and prevent relapse; however, long-term efficacy is still under investigation.

#### Key points

- There is insufficient evidence on which to base a choice between short bursts of potent topical corticosteroids compared with continuous application of mild corticosteroids.
- There is insufficient evidence for oral immunosuppressants as maintenance therapy.
- There is little evidence of a steroid-sparing effect of emollients, although these are widely prescribed.
- PUVA and UVB are effective, but there is no evidence of a clinical advantage of one modality over the other.
- Oral retinoids appear to be effective and well tolerated in hand eczema, especially in hyperkeratotic hand eczema.
- There is insufficient evidence of an additive effect of iontophoresis.
- There is insufficient evidence for a low-nickel diet or chelating agents in hand eczema accompanied by nickel allergy.
- There is insufficient evidence of an additive effect of topical antibacterial agents.
- There is insufficient evidence of the superiority of topical calcineurin inhibitors to topical corticosteroids.
- Education for secondary and tertiary prevention seems to be effective; however, long-term data are needed.

# The primary prevention of atopic dermatitis

Joanne R. Chalmers,<sup>1</sup> Sam F. Bremmer,<sup>2</sup> and Eric L. Simpson<sup>2</sup>

<sup>1</sup>Centre of Evidence Based Dermatology, University of Nottingham, Nottingham, UK

<sup>2</sup>Department of Dermatology, Oregon Health & Science University, Portland, OR, USA

## Background

### The global health burden of atopic dermatitis

The high disease prevalence, socioeconomic costs, and lack of curative therapy make the primary prevention of atopic dermatitis (atopic eczema) an important public health goal. Atopic dermatitis is a global problem increasing in prevalence in many parts of the world [1]. Prevalence rates approach 18–20% in areas of North America, Europe, and Asia. Children suffering from atopic dermatitis experience quality-of-life deficits equal to, or greater than, many chronic childhood diseases such as diabetes [2]. Children with atopic dermatitis have an increased susceptibility for developing other so-called “atopic diseases,” including food allergy, allergic rhinitis, and asthma [3]. In addition to the atopic diseases, other comorbidities associated with atopic dermatitis include a susceptibility to skin infections and sleep and psychological disturbances, especially in patients with severe disease. Whether measures that reduce the burden of atopic dermatitis also reduce the risk of these downstream consequences is not known.

### Target populations

Children at high risk for the development of atopic dermatitis remain best identified by the presence of a family history of atopic diseases, although a consensus definition of “high risk” is still lacking [4]. A parental history of atopic dermatitis specifically, as opposed to other atopic diseases, may be the strongest predictor, with the risk more than doubling in some studies [5,6]. Wen *et al.* developed a model to improve the accuracy of atopic dermatitis prediction that combines family history with environmental factors although the model needs further confirmation [7]. Filaggrin (FLG) genotype will likely play an important role in predictive models in the future. Brown *et al.* found FLG defects, especially homozygous mutations, to be highly penetrant for flexural eczema development in an unselected population-based cohort [8]. New predictive models that incorporate both FLG genotype and environmental factors utilizing birth cohorts are eagerly awaited. Several cord blood markers have also been evaluated (e.g., immu-

noglobulin E (IgE) levels, interferon-gamma, interleukin-4) but are poorly predictive of atopic dermatitis development or are not practical for routine use. Of note, while identifying high-risk populations is an important component of disease prevention, Mar and Marks estimate that a large proportion of new cases of atopic dermatitis arise from low-risk populations [9].

### Prevention approaches

Because elevated serum IgE levels commonly accompany atopic disorders, most prevention strategies have focused on preventing IgE sensitization. Indeed, multifaceted allergen avoidance strategies have been modestly successful in the primary prevention of asthma [10]. As detailed in this chapter, these allergen avoidance strategies have been less successful in the prevention of atopic dermatitis. One reason for this lack of success may be that IgE sensitization does not play a central role in the *initiation* of atopic dermatitis. In some areas of the world, flexural eczema is not associated with allergic sensitization at all [11]. Mouse models of FLG deficiency and some human studies suggest IgE sensitization may be the consequence of a skin barrier defect, with sensitization occurring through the skin [12,13]. The exact combination of factors that initiate atopic dermatitis are unknown and may vary by individual, making the design of novel prevention approaches challenging.

### Emerging research

Newer approaches to atopic dermatitis prevention are under study. The recent discovery that defects in the skin barrier gene FLG predispose to the development of atopic dermatitis has led to a renewed focus on the skin barrier in atopic dermatitis treatment and prevention [14]. Other approaches, such as attempting to alter the gut's microbiota, may help blunt pathologic inflammatory responses. Research is uncovering gene–gene and gene–environment interactions that likely contribute to disease pathogenesis [15,16]. A better understanding of how the skin barrier, the immune system, and the environment interact in this disease will hopefully lead to novel and more effective prevention strategies for all the atopic disorders.

## Methods of search

This review utilized the mapping exercise of systematic reviews for atopic dermatitis conducted by the Centre of Evidence Based Dermatology at the University of Nottingham [17]. This collection is derived from a systematic and comprehensive search of the literature that is designed to identify all systematic reviews on the epidemiology, treatment, and prevention of atopic dermatitis. Databases searched include the Cochrane Database of Systematic Reviews, Embase, and Medline/PubMed. The most recent search was performed in August 2012. Additional PubMed and Google Scholar searches were performed up to 31 October 2012 to identify individual randomized controlled trials (RCTs) published after the most recent systematic review. Our recommendations are based on the most recently published systematic review(s) that were deemed to be at least of moderate quality as assessed using the AMSTAR quality rating system [18] and any subsequently published RCTs.

## Questions

### Will exclusive breastfeeding for at least 4 months reduce a child's risk of developing atopic dermatitis?

Breast milk contains many factors that may protect against the development of inflammatory disease, such as immunoglobulins, cytokines, and omega fatty acids. Additionally, breastfeeding may establish a beneficial intestinal microbiota in the infant that protects against certain diseases [19].

#### Efficacy

Several systematic reviews and guidelines of care were identified in the literature [20–29]. Most of these reports either state that there is a protective effect of exclusive breastfeeding in the first 3–4 months of life or there is a lack of evidence. The most recent systematic review by Yang *et al.* reviewed 21 prospective cohort studies. If studies by Chandra and colleagues, which are widely viewed as fraudulent, are removed from the analyses, no protective effects were seen with exclusive breastfeeding. A large international cross-sectional study published since this review involving 51 119 children in 21 countries also found no protective effect of exclusive breastfeeding for the first 4 months of life on eczema development [30]. Additional observational cohort studies published since the Yang *et al.* review have had mixed results, with six studies showing an *increased* risk of atopic dermatitis in breastfed babies [31–36], one showing a modest protective effect only in a subset of mothers [37], and one showing no effect [38]. A tendency for families with allergy to breastfeed longer may explain the increased risk of atopic dermatitis with prolonged breastfeeding (reverse causation) [35].

#### Drawbacks

There are rare clinical situations where breastfeeding is not recommended – the metabolic condition galactosemia in the neonate, a mother with active untreated tuberculosis, maternal HIV infection, or maternal illicit drug use. In underdeveloped countries, the nutritional and immune benefits of breastfeeding a child of an HIV-infected mother may outweigh the risks of the child contracting HIV [39].

#### Comment

Studies of breastfeeding are observational in nature, as it would be unethical to perform RCTs. Therefore, recommendations cannot be

made on the highest level of evidence, and results of observational studies will always be subject to bias and confounding.

### Implications for clinical practice [clinical evidence category: unknown effectiveness]

Exclusive breastfeeding does not appear to significantly protect a child from the development of atopic dermatitis. Exclusive breastfeeding should be encouraged for the first 6 months of life, as recommended by the World Health Organization and the American Academy of Pediatrics, because of the multitude of beneficial health effects for the infant and mother [39,40]. A recent Cochrane review also concluded that the optimal duration of exclusive breastfeeding in both developed and undeveloped countries is 6 months [41].

### Can restricting the maternal diet during pregnancy or lactation prevent atopic dermatitis?

Children with atopic dermatitis have an increased risk of allergic sensitization, although the role of IgE sensitization in eczema development is unclear. Maternal dietary antigens are able to cross the placenta and can be found in breast milk. Thus, reducing exposure of these antigens to the fetus or infant was thought to reduce the chance of sensitization and possibly atopic dermatitis development.

#### Efficacy

A Cochrane systematic review (good quality) by Kramer and Kakuma, which was updated in 2012, reviewed five trials with 952 subjects [41]. Meta-analysis of two trials demonstrated no effect of food avoidance during pregnancy on the risk of atopic dermatitis development during the first 18 months of life. A previous version of this Cochrane review reported a statistically significant protective effect of antigen avoidance during *lactation*, but two studies [42,43] that are thought to contain fraudulent data were not included in the updated Cochrane review in 2012. Therefore, the updated review includes only one trial of antigen avoidance during lactation, and this trial found no protective effect.

#### Drawbacks

One trial found a statistically significant lower mean gestational weight gain with maternal dietary restriction [44]. There were statistically weak suggestions that restricting the maternal diet increases the risk of preterm birth and leads to lower birth weight.

#### Comment

There has been little research activity in this field in the past 15 years. The potential harmful effects of restricting the maternal diet will likely dissuade future research using this approach. Restricting antigen exposure is becoming a less attractive strategy given the emerging data, suggesting the potential beneficial effects of early allergen exposure [45].

### Implications for clinical practice [clinical evidence category: likely to be ineffective or harmful]

The maternal diet during pregnancy or lactation should not be restricted to prevent atopic dermatitis.

### Can administration of probiotics to the mother or baby prevent atopic dermatitis in infants and children?

Probiotics are defined as “live microorganisms which, when administered in adequate amounts, confer a health benefit on the

host” [46]. There has been a great deal of interest over the past decade in the role of probiotics for the treatment and prevention of eczema.

### Efficacy

Several systematic reviews have been published since 2007 of trials comparing probiotics with placebo for the prevention of eczema, including a Cochrane review [20,47–49], all suggesting that probiotics can reduce the risk of developing eczema; however, there were areas of weakness in the methodology of some of these reviews, such as missing trials and the inclusion of the same trial population more than once in the meta-analyses.

We identified a high-quality comprehensive systematic review published in 2012 [50] that included 13 double-blind placebo-controlled RCTs of probiotics for the prevention of eczema. All but two of these trials included infants at high risk of developing eczema based on family history of atopic disease. Results of the meta-analysis showed that probiotics can significantly reduce the risk of developing eczema compared with placebo by about 20% (relative risk [RR], 0.79; 95% confidence interval [CI], 0.71–0.90). Of the 10 trials that reported IgE-associated eczema, meta-analysis showed a similar reduction (RR, 0.80; 95% CI, 0.66–0.96). We found only one RCT that had been published since this systematic review [51] that also showed a protective effect of probiotics. In this three-arm trial, mothers received one of two probiotic combinations or placebo during pregnancy and breastfeeding. The risk of developing eczema was reduced compared with placebo in both the *Lactobacillus rhamnosus* LPR and *Bifidobacterium longum* BL999 group (odds ratio [OR], 0.17; 95% CI, 0.08–0.35) and the *Lactobacillus paracasei* ST11 and *Bifidobacterium longum* BL999 group (OR, 0.16; 95% CI, 0.08–0.35).

There is significant heterogeneity in the intervention between published trials. Only two trials have compared the same probiotic (*Lactobacillus rhamnosus* GG) and treatment regimen (mother and infant), with conflicting results [52,53]. The Kalliomäki trial of 159 infants showed that, at 2 years old, the rate of eczema was halved in the probiotic group compared with the placebo group (RR, 0.51; 95% CI, 0.32–0.84) [52]; however, Kopp *et al.* tried to replicate this finding in a trial of 105 infants and found no statistically significant difference in the rate of eczema between the two treatment groups (RR, 1.19; 95% CI, 0.68–2.09) [53].

In addition to probiotic strain variability, the recipients of the intervention varied across studies. Providing probiotics to the mother alone appears to be sufficient for a protective effect, although the theoretical protective mechanisms at work in this scenario are more difficult to explain. Subgroup analysis reported in the Pelucchi review showed a similar reduction in the rate of developing eczema, regardless of whether the mother and/or the infant received the intervention. Similarly, a review by Doege *et al.* in 2012, which only included trials that gave the probiotics to the mother and not directly to the infant, showed a similar benefit (RR, 0.82; 95% CI, 0.71–0.95) [54]. A review published in 2011 [55] only included trials of probiotic- and/or prebiotic-supplemented infant formula and concluded that there are currently insufficient data to recommend their routine use.

Further subgroup analyses by Pelucchi *et al.* examining the timing of the intervention (i.e., pre- and/or post-delivery), duration of intervention (more or less than 9 months), dose, and number of probiotic strains given showed no meaningful differences [50]. However, a subgroup analysis of different risk levels of developing eczema suggested that probiotics were more effective in preventing

eczema in infants and children with no family history of allergic disease than those at higher risk, although his meta-analysis was limited to only two trials.

### Drawbacks

The Cochrane systematic review looked in detail at the adverse effects [56]. The only significant effect found was an increase in spitting up at 1 month (RR, 1.88; 95% CI, 1.03–3.45) and 2 months of age (RR, 1.69; 95% CI, 1.02–2.80). There have been no reports of severe adverse events in any published RCT, but there is a possibility that it has not been possible to detect more rare events such as septicemia, as they have included only relatively small numbers of participants.

### Comments

It appears that probiotics can reduce the risk of developing eczema or IgE-associated eczema by about 20%, but translating this finding into practice is difficult because of the variation between trials seen in the intervention and its delivery. Between the 15 trials included here, 10 strains of *Lactobacillus* and eight strains of *Bifidobacterium* were used. In addition, seven trials gave probiotics to the mother and the baby, two to the mother only, and four to the infant only, and the duration of treatment between trials ranged from only 4 weeks up to 2 years. The only attempt to replicate a finding of one trial by using the same probiotic strain and method of administration had conflicting results. This heterogeneity makes it impossible to recommend any one treatment regimen; in fact, the SIGN guidelines on Management of Atopic Eczema in Primary Care concluded that, owing to heterogeneity in patient groups, outcomes, and probiotic strain, no recommendations could be made [21].

Future trials should attempt to replicate previous findings and establish a treatment regimen that is effective and acceptable to parents. Studies on the mechanism of action may help determine what the optimum method of administration should be. The majority of trials conducted so far have been in a high-risk population, so more trials in an unselected population are required to know whether this intervention should be recommended for the general population. Future trials should also assess the effect of probiotics on the severity and the time to onset of eczema.

### Implications for clinical practice [clinical evidence category: likely to be beneficial]

Of all the interventions studies for preventing eczema, the data on probiotics provide the best evidence of benefit, but owing to variations in the intervention used between trials, it is difficult for recommendations to be made for any one treatment regimen.

### Should fatty acid supplementation be given to mothers and neonates to prevent atopic dermatitis?

Epidemiological data support the notion that diets rich in certain omega fatty acids may have several health benefits. Omega fatty acids, especially omega-3 fatty acids, have anti-inflammatory properties. There are some observational data suggesting diets rich in omega-3 fatty acids protect against the development of atopic dermatitis. For these reasons, the role of essential fatty acids in the prevention of atopic dermatitis has been studied; namely, omega-3 and omega-6 fatty acids. These are found in high concentrations in fish and other oils.

## Efficacy

We found one high-quality systematic review on this topic. A further six RCTs were identified that had been published since this review.

The systematic review included five double-blind RCTs that evaluated the effect of omega-3 and -6 oils on the risk of developing eczema [57]. Four of the trials included only high-risk infants [58], with only one including both high- and low-risk infants [59]. Some trials gave the supplement to the mother during pregnancy or breastfeeding [59,60] and others to the infant [58,61] while still others gave the supplement to *either* the breastfeeding mother or to the infant [62]. Meta-analysis showed no effect of the supplementation; three trials of omega-3 supplementation showed a nonsignificant increase in eczema risk (RR, 1.10; 95% CI, 0.78–1.54), whereas meta-analysis of two trials with omega-6 showed a nonsignificant decreased risk (RR, 0.80; 95% CI, 0.56–1.16). Two trials reported a reduction in severity of eczema. Dunstan *et al.* showed those in the omega-3 group were 10 times less likely to develop severe eczema (OR, 0.09; 95% CI, 0.01–0.94) [60]. Van Gool *et al.* showed a decreased SCORAD in the omega-6 group (mean plus/minus standard deviation [SD],  $6.32 \pm 5.32$ ) compared with the control group (mean  $\pm$  SD,  $8.28 \pm 6.54$ ) [58].

An RCT published in 2009 randomized 145 pregnant women to receive either omega-3 supplementation or placebo during late pregnancy and while breastfeeding [63]. The study showed a statistically significant reduction in IgE-associated eczema at 12 months (4/52 vs 15/63;  $P = 0.02$ ). When these high-risk infants were followed up at 2 years of age, a statistically significant reduction in the cumulative incidence of IgE-associated eczema remained (5/54 vs 15/63;  $P = 0.04$ ), but no difference was seen in the incidence of “any eczema” [64].

In another RCT, Linnamaa *et al.* gave blackcurrant seed oil, which is rich in omega-3 and -6 fatty acids, or placebo to 322 mothers during pregnancy and while breastfeeding, as well as to the infants up to 2 years of age [65]. There was a statistically significant reduction in the number of children with eczema at 1 year of age (33% vs 47.3%;  $P = 0.035$ ), but this significance was lost by 2 years of age (38.8% vs 48.9%;  $P = 0.18$ ).

In another high-risk population, Palmer *et al.* randomized 706 mothers to receive fish oil or placebo during pregnancy [66]. They observed a significant reduction in the number of infants with IgE-associated eczema at 1 year of age (RR, 0.61; 95% CI, 0.38–0.98). In contrast, D’Vaz *et al.* randomized 420 high-risk infants to receive daily fish oil supplement or placebo until the age of 6 months [67]. At 12 months they were assessed for eczema and found no difference between the two groups.

Lastly, in an RCT published in 2012, the authors used dietary advice to supplement with essential fatty acids [68]. They randomized 123 mothers to advice to consume oily fish (salmon) twice a week or continue with their existing diet during pregnancy. Eighty-six infants were assessed at 6 months for eczema and no significant difference between the two groups was found in the incidence of eczema (25.0% vs 18.4%;  $P = 0.46$ ) or the severity (mean  $\pm$  SD,  $7.4 \pm 3.5$  vs  $10.0 \pm 8.9$ ;  $P = 0.37$ ).

## Drawbacks

While it could be assumed that essential fatty acids would not have an adverse effect, none of the trials reported on safety. Recent studies reveal n-6 omega fatty acids could have a pro-carcinogenic effect [69].

## Comments

There are a number of good-quality RCTs on this topic, but the conclusions drawn differ between trials. The systematic review suggested that omega-3 and -6 fatty acids are not an effective intervention for preventing eczema, but several RCTs have been published since this review, some of which suggest there may be a preventative effect. Additionally, there is variation in the intervention between trials; in some, the supplement is given to the mother, in others the infant, and in others to the mother and the infant [62]. This may explain some of the differences observed, because most of the RCTs reported were conducted in high-risk infants, so it is unclear how these findings would translate to the wider population.

## Implications for clinical practice [clinical evidence category: unknown effectiveness]

The intervention varies between trials and the results of the trials are variable, so it is difficult to make firm recommendations for clinical practice.

## Should the introduction of complementary foods to the infant be delayed to prevent the development of atopic dermatitis?

Reducing exposure to food allergens early in life was thought to prevent IgE sensitization despite a paucity of supporting data. By reducing food sensitization, researchers hoped to reduce the risk of atopic dermatitis development. Recent data suggest that delaying exposure to food antigens may actually *increase* the risk of IgE sensitization. There may be a window of opportunity during infant development for the induction of immune tolerance via oral exposure [70].

## Efficacy

There were no systematic reviews of RCTs or individual RCTs available for review. A systematic review (moderate quality) of nine observational studies reporting on six cohorts by Tarini *et al.* published in 2006 concluded that the early introduction of solid food before 4 months of age *may* increase the risk of eczema development [71]. Tarini *et al.* also commented that the majority of studies were poorly designed and were susceptible to bias. Since the Tarini *et al.* review, four observational studies have been reported, with three of these showing a *reduced* incidence of atopic dermatitis with early introduction of solid food [37,72,73] and one showing no effect [74].

## Drawbacks

The question of delaying the introduction of solid food is likely more relevant to the development of food allergy than to atopic dermatitis development. Delaying the introduction of solid food may actually *increase* the risk of food allergy. Emerging data reveal early oral exposure to food allergens may induce tolerance [70]. Previous guidelines by the American Academy of Pediatrics and the UK Health Service recommending the strict avoidance of allergenic foods until 1–3 years of age were not based on robust data and these recommendations have since been retracted [29,41].

## Comment

Despite previous recommendations to the contrary, delaying the introduction of solid foods beyond 6 months does not prevent atopic dermatitis and may increase the risk of food allergy. The best approach for introducing allergenic foods (e.g., peanut, egg, soy, fish) for children with atopic risk factors is not known. The Learning

Early About Peanut Allergy study ([www.leapstudy.co.uk](http://www.leapstudy.co.uk)) and the Enquiring About Tolerance study ([www.eatstudy.co.uk](http://www.eatstudy.co.uk)) are two large ongoing RCTs examining whether early introduction of allergenic foods protects or promotes atopic dermatitis and food allergy. Initial results are expected in 2014.

### **Implications for clinical practice [clinical evidence category: likely to be ineffective or harmful]**

Parents should be instructed to gradually introduce foods beginning around 6 months of age. Although no data are available to guide food introduction in children with a family history of atopic disease (i.e., high risk), it would be prudent to introduce allergenic foods in small volumes one at a time, at a minimum of 4-day intervals. Foods should be given at home with antihistamines available [75]. Immediate medical care should be sought if symptoms of immediate hypersensitivity are observed. The Food Standards Agency in the UK recommends seeking counsel with a health-care provider prior to introducing peanut protein in children with a first-degree relative with atopic disease [76].

### **If exclusive breastfeeding is not possible, should a hydrolyzed formula be used to prevent atopic dermatitis in high-risk infants?**

Hydrolyzed formulas are thought to reduce the risk of IgE sensitization to milk protein in at-risk neonates. The food allergy guidelines published by the National Institutes of Health in 2010 found only a moderate level of evidence that hydrolyzed formulas can reduce cow milk sensitization in high-risk neonates, but found they do not have an effect on the sensitization to other food antigens. The relationship between cow milk sensitization and the development of atopic dermatitis is unclear.

### **Efficacy**

Four recent systematic reviews and one government-sponsored health claim review were identified that evaluated the role of hydrolyzed formulas in atopic dermatitis prevention [77–81]. The Cochrane review (high quality) found no statistically significant effect of hydrolyzed formula compared with cow's milk formula with the exception of a subgroup analysis of three studies of extensively hydrolyzed casein formula. Osborn and Sinn [77] concluded that, owing to "methodological concerns," better RCTs are needed. A systematic review published in 2010 by Alexander *et al.* [78] (moderate quality), which was partially funded by the Nestle Corporation, found the use of *partially* hydrolyzed whey protein formula reduced the incidence of atopic dermatitis compared with standard cow milk formula. A systematic review by Szajewska and Horvath [80] (moderate quality) published in 2010, also funded by Nestle, found a protective effect of *partially* hydrolyzed whey formula on atopic dermatitis development. Szajewska and Horvath's review only included studies that used formulas manufactured by Nestle, however. The US Food and Drug Administration (FDA) undertook a qualitative assessment of all systematic reviews and meta-analyses to evaluate a "qualified health claim" proposal by Nestle in 2011. They concluded that "there is little to very little credible evidence for a qualified health claim about W-PHF [partially hydrolyzed whey formula] and a reduced risk of AD [atopic dermatitis]," although the FDA *did* accept a qualified health claim for the product [82]. Since the publication of these reviews, a randomized controlled study of 620 high-risk infants was reported by Lowe *et al.*, who found no reduction in the incidence of eczema or

any atopic disease at 2 years with the use of partially hydrolyzed whey formula or soy formula [82].

### **Drawbacks**

Potential drawbacks of the use of hydrolyzed formulas include the incorrect perception of hypoallergenicity, potential adverse effects on growth, poor palatability, and cost. A significant percentage (up to 50%) of infants with true milk allergy experience allergic reactions to partially hydrolyzed whey formulas [83–85]. Some studies involving preterm infants have shown reduced growth rates with the use of hydrolyzed formulas [86,87], although these effects have not been seen in term infants. Issues with palatability and compliance with hydrolyzed formulas have been reported [88–90]. The cost of *extensively hydrolyzed* formulas is also significantly more than standard cow milk formula, although the use of *partially hydrolyzed* whey formula showed a cost benefit in atopic dermatitis prevention in at least one study [91].

### **Comment**

The conflicting results and conclusions of the reviews result primarily from differences in how studies were selected for inclusion. For example, Osborn and Sinn excluded a study by Chan showing positive effects of a hydrolyzed formula because of excess loss to follow-up, while Alexander *et al.* included this study in the analysis. The two largest, most recent, and best-reported RCTs have conflicting results [82,92]. The German Infant Nutritional Intervention study, the highest quality RCT performed to date, found upon intent-to-treat analysis that the use of partially hydrolyzed whey formula had a significant effect on eczema prevention, but paradoxically did not see a protective effect for the extensively hydrolyzed whey formula. The RCT by Lowe *et al.* did not find a protective effect of partially hydrolyzed whey formula [82].

### **Implications for clinical practice [clinical evidence category: unknown effectiveness]**

There is some evidence supporting the use of a partially hydrolyzed whey formula for the primary prevention of atopic dermatitis in high-risk infants. This approach can be considered for infants when exclusive breastfeeding is not possible in the first 6 months of life. Given the significant cost, poor palatability, and inconsistency of the data, the use of extensively hydrolyzed formula cannot be recommended for atopic dermatitis prevention at this time.

### **Should dust mite avoidance measures be used to prevent the development of atopic dermatitis?**

Several studies have shown patients with atopic dermatitis are commonly sensitized to house dust mite and have more dust mites in their environment compared with controls. In contrast, the only prospective cohort study of >500 newborns found *no correlation* between house dust mite antigen exposures and atopic dermatitis development [93].

### **Efficacy**

No systematic reviews were identified. Our search yielded five prospective trials addressing the utility of dust mite avoidance in the primary prevention of atopic dermatitis in infants with a family history of atopy. Three trials looked at dust mite avoidance strategies alone, while two evaluated a multifaceted approach of dust mite avoidance combined with a hypoallergenic diet.

The largest trial ( $n = 721$ ) compared the use of mite-impermeable mattress covers starting at the third trimester on the parents' and

infant's beds against cotton (placebo) covers in a double-blind fashion [94]. Overall, there was a slight trend toward an *increased* risk of atopic dermatitis by history (RR, 1.05; 95% CI, 0.86–1.29) in patients using mite-impermeable covers, a difference that was statistically significant at the last time point.

An unblinded study ( $n = 516$ ) comparing dust-mite-impermeable mattress covers, acaricide use, and supplying a washable play mat with a no intervention control group also demonstrated a significantly *increased* risk of atopic dermatitis by physical exam (20.6% vs 13.7%;  $P = 0.03$ ) and by a questionnaire (33.5% vs 25.3%;  $P = 0.04$ ) at 18 months [95]. At 5-year follow-up, current atopic dermatitis (25.7% vs 18.5%;  $P = 0.06$ ) and a history of physician-diagnosed eczema (34.8% vs 23.9%;  $P = 0.009$ ) remained more common in the intervention group [61]. A small study ( $n = 251$ ) comparing mattress covers, acaricides, and vinyl flooring against no intervention found a similar prevalence of atopic dermatitis at 1 year in the intervention and control groups (40% vs 37%;  $P$  value not reported) [96].

The smallest study identified ( $n = 120$ ) evaluated the use of mattress covers, acaricides, and a restrictive diet where the breastfeeding mother and infant were asked to avoid foods containing dairy, egg, wheat, nuts, fish, and soy for the first 12 months of life, compared with a non-intervention control group [97]. At 8-year follow-up, there was a trend toward a decreased risk of atopic dermatitis in the intervention group (36.2% vs 46.8%;  $P = 0.16$ ), which achieved statistical significance when the data were adjusted for multiple confounders (OR, 0.23;  $P = 0.005$ ). These results were not replicated in a larger study ( $n = 696$ ) comparing the use of mattress covers and a book explaining allergen avoidance measures (exclusive breastfeeding or use of a hypoallergenic formula until 3 months, avoidance of wheat and cow's milk until 6 months, avoidance of egg and fish until 12 months, avoidance of peanuts and tree nuts until 3 years, removal of carpets from the infant's room, and weekly vacuuming), against a group given a control booklet [98]. The risk of physician diagnosis of eczema was similar in the intervention and control groups (18.8% vs 21.1%;  $P = 0.516$ ).

### Drawbacks

Dust-mite-impermeable mattress covers are relatively innocuous, although the studies by Gehring's and Mihrshahi's groups do raise the possibility of dust mite avoidance potentially promoting the development of atopic dermatitis.

### Comment

Overall, the studies were relevant to this clinical question, adequately powered and of relatively good quality, including one large double-blind, placebo-controlled trial. Although there was an opportunity for bias in the unblinded trials, one would expect this to skew the results to show a protective effect of dust mite avoidance strategies, which was generally not present. Rather, there was a significantly increased risk of atopic dermatitis by some measures in two large studies, compared with a significantly decreased risk in the adjusted data of the smallest study.

### Implications for clinical practice [clinical evidence category: likely to be ineffective or harmful]

Although one small study has shown some benefit of dust mite avoidance in the prevention of atopic dermatitis, larger studies and one double-blinded, placebo-controlled trial have shown them to increase the risk of atopic dermatitis development or to not be helpful. Dust mite avoidance measures should not be recommended for the primary prevention of atopic dermatitis.

## Does early emollient use prevent the development of atopic dermatitis?

There is increasing evidence that the primary event in the development of eczema is a defective epidermal barrier, which allows allergens and irritants to enter the body and trigger the inflammatory response [99]. Therefore, it is logical to consider whether regular application of emollient from birth may enhance the skin barrier sufficiently to prevent eczema from developing.

### Efficacy

Despite their widespread use in *treating* eczema, there is very little published evidence on the role of emollient therapy in *preventing* eczema. We found no published systematic reviews on the role of emollients for the prevention of eczema. We did identify two small pilot RCTs (both published in abstract form only), one open-label prospective study and one case-control study that looked at simple emollients for the prevention of eczema.

A pilot RCT carried out in the UK and the USA by Simpson *et al.* randomised 124 newborn infants at high risk of atopic disease to receive either daily emollient plus skin care advice or skin care advice alone [14]. An intention-to-treat analysis of the 6-month cumulative incidence of a blinded assessment of eczema status showed a reduction in the rate of eczema in the emollient group; the OR of developing eczema in the emollient group compared with the control group was 0.37 (95% CI, 0.14–0.91;  $P = 0.017$ ). Conversely, a second small pilot RCT conducted in Japan that randomized 71 babies at high risk of atopic disease to either emollients plus instructions on skin care or control found no difference between the two groups in the rate of eczema during the first 6 months of life in a per-protocol analysis [100]. However, they did show that there were fewer children with positive reaction to skin prick tests in the emollient group. In a prospective open-label pilot study by Simpson *et al.*, 22 babies at high risk of developing eczema were enrolled [101]. Parents were instructed to apply a petrolatum-based cream to their infant at least once a day and the mean follow-up time was 547 days. The proportion of children developing eczema was 15%, which is between 15 and 35% lower than expected in this high-risk group, suggesting a protective effect of the emollient. A case-control study published in 1991 including 54 Kenyan children with eczema and 63 matched controls [102] found that the odds of developing eczema were reduced by application of petrolatum in early life (OR, 0.33; 95% CI, 0.14–0.80).

### Drawbacks

Although there is a lack of evidence regarding safety, it is unlikely that emollients will cause harm in this setting. Several groups have shown that regular application of emollients can improve the condition of the immature skin of preterm neonates, reduce the amount of dermatitis, and does not result in harmful side effects [103–108]. However, it is possible that occlusion as a result of applying emollients daily from birth could result in adverse effects such as folliculitis and skin infections. A case-control study by Campbell *et al.* found petrolatum use on the skin increased the risk of systemic candidiasis in extremely low birth weight infants [109]. No increase in cutaneous infections or other adverse events occurred in the three trials of emollient therapy for eczema prevention mentioned above, although the pilot RCT by Kataoka and colleagues did not specifically report on the safety of emollients [100].

### Comments

Since the discovery of mutations in the gene encoding FLG, a key skin barrier protein, and the strong association of FLG mutations

with allergic disease [110,111], there has been a great deal of interest in interventions that target the skin barrier to prevent eczema [112]. However, there is currently no high-level evidence on this topic, so there is a need for further RCTs to be conducted. They should be adequately powered to detect a response; those published so far are only small pilot RCTs, which may explain the difference in findings. Additionally, in both these RCTs the infants were only followed up for 6 months; future trials should aim for at least 2 years of follow-up to distinguish eczema from the many eczematous rashes seen in young babies. Trials should also assess the severity and time of onset of eczema to determine whether emollients can reduce the severity or delay the onset. Finally, it is important that trials of existing simple, cheap emollients are carried out, as well as trials of the newer, more state-of-the-art emollients that are now being marketed.

### Implications for clinical practice [clinical evidence category: unknown effectiveness]

There is currently insufficient evidence to recommend the use of emollients to prevent eczema. There is a suggestion that emollients could be effective, but the evidence is weak and more high-quality data regarding the safety and effectiveness of emollients applied daily from birth are needed before any recommendations can be made.

#### Key points

- Despite decades of research, no single strategy has emerged as clearly effective for atopic dermatitis prevention.
- Although the effect is modest (20% reduction), probiotics appear to have the strongest evidence for a protective effect. However, it is difficult to recommend any one strain of probiotic or treatment regimen because of the heterogeneity between trials.
- There is a modest level of evidence to support the use of partially hydrolyzed whey formulas for atopic dermatitis prevention in high-risk infants who are unable to exclusively breastfeed for the first 4–6 months of life.
- Given the conflicting data, omega fatty acid supplementation cannot be strongly recommended for atopic dermatitis prevention.
- Restricting the maternal or infant diet is not protective and should not be recommended.
- Delaying the introduction of solid foods does not prevent atopic dermatitis and theoretically could increase the risk of food allergy development.
- Dust mite avoidance measures should not be recommended for atopic dermatitis prevention.
- Emollients are a promising intervention for preventing eczema, but the evidence available is insufficient to make any recommend their use and there is a need for large RCTs.

# Atopic eczema

Kim Thomas, Carolyn Charman, Helen Nankervis, Jane Ravenscroft, and Hywel C. Williams

Centre of Evidence-Based Dermatology, University of Nottingham, Nottingham, UK

## Coverage and main data sources

Since over 200 types of interventions belonging to 12 broad categories have been tried in atopic eczema (synonymous with atopic dermatitis), complete coverage of all therapy-related issues for atopic eczema is not possible, even in a chapter of this size. Instead, we have opted to introduce the evidence base for treating atopic eczema by means of three common clinical scenarios:

- Case scenario 24.1: a child with moderately severe atopic eczema.
- Case scenario 24.2: a person with clinically infected atopic eczema.
- Case scenario 24.3: an adult with severe atopic eczema.

Much of the background work and methodology within the sections has been based (with appropriate updates) on the results of a systematic review of eczema treatments funded by the UK National Institute of Health Research (NIHR) Programme Grant for Applied Research, which has resulted in a comprehensive database of all randomized controlled trials (RCTs) of eczema called the Global Resource for Eczema Trials (GREAT) database (<http://www.greatdatabase.org.uk/>). The GREAT database is free for all to access in the public domain and it builds on a previous overarching systematic review of atopic eczema treatments, which was published at the end of 2000 (<http://www.hta.ac.uk/fullmono/mon437.pdf>). Readers are recommended to check with the GREAT database as more RCTs are added in what has now become a rapidly moving field. Additional information on systematic reviews on atopic eczema has been gleaned from a summary mapping exercise of all eczema systematic reviews which has been conducted at the Centre of Evidence-Based Dermatology at the University of Nottingham (<http://www.nottingham.ac.uk/dermatology>).

## Background

### Definition and diagnostic criteria

Atopic eczema (atopic dermatitis) is a chronic inflammatory skin condition characterized by an itchy red rash that favors the skin creases, such as the folds of the elbows, behind the knees, and around the neck. The morphology of the eczema lesions varies in appearance from vesicles and oozing to gross lichenification on a background of poorly demarcated redness. Other features such as

crusting, scaling, cracking, and swelling of the skin can occur [1]. Atopic eczema is associated with other atopic diseases such as hay fever and asthma, although such associations may reflect shared environmental causes, as opposed to genetics. People with atopic eczema also have a tendency to have a dry skin, which increases their vulnerability to the irritant effects of soaps. Much of the dry skin tendency might be secondary to deficiencies in filaggrin protein expression, which is genetically determined and important in white European populations [2,3].

Atopic eczema typically starts in early life, with about 80% of cases starting before 5 years of age [4]. Although the word “atopic” is used when describing atopic eczema, it should be noted populations studies show that anything from 20% to 100% of people with otherwise typical atopic eczema are not atopic as defined by the presence of positive skin-prick test reactions to common environmental allergens or through blood tests that detect specific circulating immunoglobulin E (IgE) antibodies [5,6]. The role of atopy in atopic eczema has been systematically reviewed elsewhere [7]. The word “atopic” in the term “atopic eczema” is simply an indicator of the frequent association with atopy (especially in more severe hospital populations in developed countries) and the need to separate this clinical phenotype from other forms of eczema, such as irritant or allergic contact eczema, which have other causes and distinct patterns. The terms “atopic eczema” and “atopic dermatitis” are synonymous. The term “atopic eczema,” or just “eczema,” is frequently used in the UK, whereas the term “atopic dermatitis” is used more in the USA. Much scientific energy has been wasted in debating which term should be used, culminating in the World Allergy Organization proposal for a revised nomenclature [8].

Very often, no definition of atopic eczema is given in clinical studies such as clinical trials. This leaves the reader guessing as to what sort of people were studied. Atopic eczema is a difficult disease to define, as the clinical features are highly variable with regard to morphology, body site, and time. There is no specific diagnostic test encompassing all people with typical eczema that can serve as a reference standard. The diagnosis is, therefore, essentially a clinical one.

At least 10 synonyms for atopic eczema were in common usage in the dermatology literature in the 1970s, and it is doubtful whether physicians were all referring to the same disease. A major

**Box 24.1**

In order to qualify as having a case of atopic eczema, the person must have an itchy skin condition plus three or more of the following [11]:

- past involvement of the skin creases, such as bends of elbows or behind the knees;
- a personal or immediate family history of asthma or hay fever;
- a tendency towards a generally dry skin;
- onset under the age of 2 years;
- visible flexural dermatitis, as defined by a photographic protocol.

development in describing the main clinical features of atopic eczema was the Hanifin and Rajka diagnostic criteria (1980) [9]. These criteria are frequently cited in clinical trial articles, and they at least provide some degree of confidence that researchers are referring to a similar disease when using these features. It should be borne in mind, however, that these criteria were developed on the basis of consensus based on experience with seeing more severe cases in a hospital setting [5]. Some of the minor features have since been shown not to be associated with atopic eczema, and many of the terms, which are poorly defined, probably mean something only to dermatologists. Scientifically developed refinements of the Hanifin and Rajka diagnostic criteria, mainly for epidemiological studies, have been developed by a UK working party, and these criteria have been widely used throughout the world and in clinical trials (Box 24.1) [10,11]. The UK refinement of the Hanifin and Rajka criteria have been the most widely validated criteria worldwide, as summarized in a systematic review [12].

It is quite possible that there are distinct subsets of atopic eczema – for example, those cases associated with atopy, those forms associated with early wheezing [13], those associated with defective filaggrin expression [2], and patients who have severe disease with recurrent infections. Until the exact genetic and causative agents are known, it is prudent to consider the clinical disease as one condition. Perhaps prespecified sensitivity analyses should be done within clinical trials, if large enough, for those who are thought to represent distinct subsets – for example, those with filaggrin gene mutations, those with severe disease and associated asthma, and those who are definitely atopic with raised circulating IgE to allergens – especially for trials of certain interventions, such as reducing house dust mites or food exclusions, where the presence of prior sensitization might be key [5].

### **Incidence/prevalence**

Atopic eczema is a very common problem. European prevalence studies conducted during the last 10 years suggest an overall prevalence of 15–20% in children aged 7–18 years [14]. Standardized questionnaire data from almost a million children aged 6–7 years and 13–14 years in the International Study of Asthma and Allergies in Childhood suggest that atopic eczema is not just a problem confined to western Europe, with high prevalences being found in many developing cities undergoing rapid demographic change [15]. There is reasonable evidence to suggest that the prevalence of atopic eczema has increased in many countries over the last 10 years, although the reasons for this are unclear [16].

Atopic eczema is more frequent in childhood, especially in the first 5 years of life. One study of 2365 patients in Livingston, Scotland, who were examined by a dermatologist for atopic eczema, suggested that atopic eczema is relatively rare over 40 years of age,

with a 1-year period prevalence of 0.2% [17]. Yet, because there are many more adults than children, they may make up over 38% of all atopic eczema cases in that community. Adults also tend to represent a more persistent and severe subset of cases.

Most cases of childhood eczema in any given community are mild. One study found that 84% of 1760 children aged 1–5 years from four urban and semi-urban family practitioners around Nottingham, England, were mild, as defined globally by the examining physician, with 14% of cases in the moderate category and 2% in the severe category [18] – a severity distribution that was very similar to that in another population survey in Norway [19].

### **Morbidity and costs**

Atopic eczema usually accounts for the worst disturbance in quality of life in comparison with other dermatological diseases. Specific aspects of a child's life affected by atopic eczema are [14]:

- itch and its associated sleep loss (which can also cause considerable family disturbance);
- social stigmatization from other children and parents;
- the need for special clothing and bedding;
- avoidance of activities such as swimming;
- the need for frequent applications of topical treatments and visits to health-care professionals.

In financial terms, the cost of atopic eczema is potentially very large. One study of an entire community in Scotland in 1995 estimated that the annual personal costs to patients with atopic eczema was £297 million (US\$606 million), if extrapolated to the entire UK [20]. The cost to the National Health Service was £125 million, and the annual cost to society through lost working days was £43 million, making the total expenditure on atopic eczema £465 million per year (US\$949 million). This figure is likely to be an underestimate, since the prevalence of atopic eczema is lower in Scotland in comparison with the rest of the UK. Another study from Australia found that the annual personal financial cost of managing mild, moderate, and severe eczema was A\$330, A\$818, and A\$1255, respectively, which was greater than the costs associated with asthma in that study [21]. One systematic review that tried to estimate the national costs of eczema in the USA found four informative studies with annual costs (direct plus indirect) estimated to be between US\$364 million and US\$3.8 billion per year in 2008 [22].

### **Etiology**

#### **Genetics**

There is strong evidence to suggest that genetic factors are important in the predisposition to atopic eczema. Twin studies have shown a much higher concordance for monozygotic (85%) than for dizygotic twins (21%) [23]. Genes coding for filaggrin proteins have been the strongest and most consistent marker of increased eczema risk in several populations [24,25], and such mutations are also associated with more severe and persistent disease and more asthma [26]. Other genes coding for immune response and the ability to deal with *Staphylococcus aureus* may be important [24], and it is possible that the tendency to atopic eczema might be inherited independently from atopy [27].

#### **Environment**

There are several general and specific clues that point strongly to a role of the environment in disease expression [28]. It is difficult to explain the large increase in the prevalence of atopic eczema over the past 30 years in terms of genetics [16]. It has been shown that

atopic eczema is more frequent in wealthy families [29]. It is unclear whether this positive social class gradient reflects exposure to indoor allergens or whether it reflects a whole constellation of other factors associated with social “development.” Other studies have shown an inverse association between the prevalence of eczema and family size [30]. This observation led to the “hygiene hypothesis” – that children in larger families were “protected” from expressing atopy because of frequent exposure to infections [31]. Some evidence for this “protective” effect of infections on atopic eczema has been shown in relation to measles infection [32]. The link between fewer infections (bacterial or helminthic) and increased eczema has been reviewed comprehensively elsewhere [33].

Migrant studies also point strongly to the role of environmental factors in atopic eczema. For example, 14.9% of black Caribbean children living in London develop atopic eczema (according to the UK diagnostic criteria), in comparison with only 5.6% of similar children living in Kingston, Jamaica [34].

Further work has suggested that the tendency to atopy may be programmed at birth and could be related to factors such as maternal age [35]. The observation that many cases of atopic eczema improve spontaneously around puberty is also difficult to explain in genetic terms alone [4]. Specific environmental risk factors for the expression of eczema are still not fully elucidated [36]. Allergic factors such as exposure to house dust mite may be important, but nonallergic factors such as exposure to irritants, bacteria, and hard water may also be equally important [37].

### Pathophysiology

There appears to be a failure to switch off the natural predominance of T-helper 2 lymphocytes that occurs in infancy, which leads to an abnormal response of chemical messengers called cytokines to a variety of stimuli [1,38]. The underlying mechanism of disease may be abnormalities in cyclic nucleotide regulation of marrow-derived cells or allergenic overstimulation, causing secondary abnormalities [39]. Some studies have demonstrated a defect in lipid composition and barrier function in people with atopic eczema – a defect that is thought to underlie the tendency to dry skin and possibly the enhanced penetration of environmental allergens and irritants, leading to chronic inflammation.

### Prognosis

The majority of children with atopic eczema appear to “grow out” of their disease, at least to the point where the condition becomes a problem no longer in need of medical care. A detailed review of prognostic studies reported elsewhere [4] concluded that most large studies of well-defined and representative cases suggest that about 60% of childhood patients are clear or free of disease symptoms in early adolescence. However, many such apparently clear cases are likely to recur in adulthood, often as hand eczema. The most consistent factors that appear to predict persistent atopic eczema are early onset, severe widespread disease in infancy, concomitant asthma or hay fever, and a family history of atopic eczema. One birth cohort study of 1314 children followed to age 7 years in Germany (The Multicenter Allergy Study) found that of the 21.5% of children with eczema in the first 2 years of life, 43.2% were in remission by age 3 years, 38.3% had intermittent disease, and 18.7% had symptoms every year. Poor prognosis was related to IgE sensitization and early disease severity. Early eczema without early wheezing did not increase the risk of subsequent wheeze at school entry age (adjusted odds ratio, 1.11; 95% confidence interval [CI], 0.56–2.20) [13].

### Aims of treatment

Cure is an unrealistic option for the majority of sufferers, as it is so unusual for there to be a single, treatable cause for atopic eczema, such as a specific food allergy. In addition, the effect of conventional treatment on the long-term natural history of the disease is simply not known. Treatment is thus aimed at relieving troublesome symptoms such as itch and soreness and its associated sleep loss, in order to improve the person's quality of life. Improvement in skin appearance may also be important, as is self-esteem, social confidence, and the ability to participate freely in recreational activities such as swimming. In addition to short-term relief of symptoms, recent interest has focused on disease modification strategies and prevention of flares as part of proactive long-term control which are discussed later in this chapter [40,41].

### Relevant outcomes

Outcome measures used in trials have been reviewed by Finlay [42]. Most outcome measures have incorporated some measure of itch, as assessed by a doctor at periodic reviews or patient self-completed diaries. Other more sophisticated methods of objectively recording itch have been tried. Finlay drew attention to the profusion of composite scales used in evaluating atopic eczema outcomes. These usually incorporate measures of the extent of atopic eczema and several physical signs, such as redness, scratch marks, thickening of the skin, scaling, and dryness. Such signs are typically mixed with symptoms of sleep loss and itching, and variable weighting systems are used. It has been shown that measuring surface area involvement in atopic eczema is fraught with difficulty [43] – which is not surprising, considering that eczema is, by definition, “poorly defined erythema.” Charman and Williams carried out a systematic review of named outcome measure scales for atopic eczema and found that of the 13 named scales in current use, only one (scoring atopic dermatitis, SCORAD) had been fully tested for validity, repeatability, and responsiveness [44]. A further systematic review of 20 named scales used to measure eczema severity found that only three – SCORAD, eczema area and severity index (EASI), and patient-orientated eczema measure (POEM) – had been tested sufficiently and performed adequately when tested [45]. Quality-of-life measures specific to dermatology include the dermatology quality of life index [46] and Skindex [47]. The children's dermatology life quality index (CDLQI) has been used in atopic eczema trials in children. Subsequent work by Charman *et al.* has resulted in the development of the patient-oriented outcome measure known as POEM – an outcome that measures items that are deemed to be important for patients and which can also be used for rapid monitoring in routine clinical practice [48].

Most clinical trials of atopic eczema have been very short (i.e., about 6 weeks), which seems inappropriate in a chronic relapsing condition [49]. Few studies have considered measuring the number and duration of disease-free periods, apart from a few exceptions in the use of topical calcineurin inhibitors and “weekend” treatment for topical corticosteroids. In the absence of such long-term studies, it is impossible to say whether modern treatments have increased chronicity at the expense of short-term control. The definition of a “flare” of atopic eczema is problematic and has been reviewed by Langan *et al.*, who also propose a series of long-term outcomes such as the number of “well-controlled weeks,” analogous to long-term asthma outcomes [50]. As a result of the profusion of outcomes in eczema and inappropriate emphasis on short-term changes, an international group called the Harmonizing Outcome Measures for Eczema (HOME, <http://www.homeforeczema.org/>)

group has formed to try to define a short list of core outcome sets that should be used in all future atopic eczema trials. Early work using an international Delphi process has identified four domains, including symptoms, signs, long-term disease control, and quality of life [51].

## Questions

### Case scenario 24.1: a child with atopic eczema of moderate severity

Figure 24.1 shows a child with atopic eczema.

#### What is the role of emollients?

##### *Efficacy*

Current clinical guidelines recommend “complete emollient care” including leave-on emollients, soap substitutes and bath emollients [52,53]. Despite limited evidence for any of these products, clinical opinion is generally supportive of the liberal use of emollient therapy for the management of eczema.

Since the last edition of this book, there has been renewed interest in the topic of emollient therapy for eczema and we identified 33 RCTs that included emollient therapy as either the active or the control intervention. Further details of these trials are summarized in Web Table 24.1. Overall, five of the trials compared emollients with no emollients [54–58]; 16 compared one emollient with another [59–74]; 10 trials compared emollients with topical corticosteroids or calcineurin inhibitors [75–84]; and two trials compared emollients with other active eczema treatments [85,86]. Trials on the use of bath emollients are discussed in the section on washing and bathing.

A particular focus of recent studies has been on the potential steroid sparing capabilities of emollients, where two reasonably large studies ( $n = 173$  and  $n = 162$  respectively) comparing emollient therapy with no emollient therapy have suggested possible steroid-sparing effects, with no apparent increase in eczema severity [55,56].

Three studies have looked at the use of maintenance therapy and the role of emollients in preventing eczema flares. One trial compared maintenance therapy with topical corticosteroid plus emollients against emollient therapy alone (control), and a second

compared maintenance with a calcineurin inhibitor (tacrolimus 0.03% or 0.1%) against emollient therapy alone [78,84]. Both of these trials favored active treatment compared with emollients alone and are discussed further in the sections on topical corticosteroids and calcineurin inhibitors. A third trial looked explicitly at the ability of emollients to prevent eczema flares in 44 adults with eczema [57]. In this parallel group RCT, emollient therapy (Canoderm® cream) was applied to a single site twice daily until relapse (or until the end of 6 months), compared with no use of emollients at a target site. Median time to relapse for the emollient group was over 180 days (length of the study) compared with 30 days in the no-emollient group. The proportion of participants who remained eczema free for the entire 6-month maintenance phase was 68% in the emollient group and 32% in the no-emollient group.

##### *Drawbacks*

Adverse effects from emollients are generally poorly reported in clinical trials, although most side effects that have been reported were mild (including transient burning), or relate to cosmetic acceptability.

There are currently many brands of emollients available, and new, expensive “barrier-enhancing” products are emerging. Whether the additional cost of these products is warranted compared with simpler and relatively cheap alternatives remains to be seen, and large pragmatic studies are required to establish the relative cost effectiveness of different products.

##### *Comments*

Whilst it is pleasing to see the number of emollient trials expanding, the lack of reporting of methodological detail and the seeming lack of regard for addressing the most clinically pressing issues is disappointing. It is questionable whether testing emollients in RCTs is needed and ethical given that they are so deeply engrained in medical practice. Some may argue that the point of equipoise has passed. Yet, given that some emollients such as aqueous cream may actually cause harm [87], it is important to recognize that some products may be more beneficial than others, and that a range of products may be needed for different parts of the body and for different skin types and ages.

The effects of emollients as part of a package of care are difficult to assess, and need to be long term in order to pick out any possible subtle benefits such as prevention of flares. The current body of evidence does appear to support the use of emollients in the management of eczema, and lends weight to the suggestion that it does not necessarily matter which emollient you choose as long as one is used.

Future research into which emollients are best, how much emollient to use, when to apply it, and how best to ensure adherence with topical medications is now warranted.

##### *Implications for clinical practice*

There is currently no evidence to doubt the belief that regular emollient use is beneficial for the treatment of the dry skin associated with atopic eczema, and there is some evidence to suggest that regular emollient use can prevent eczema flares and reduce the amount of topical steroid needed. Given the huge variety of emollients currently available and the widely varying costs, further research would be helpful to establish which products are most cost effective and most acceptable to patients.

Figure 24.1 A child with atopic eczema.

**Key points: emollients**

- Thirty three RCTs have been summarized. Five trials compared emollient therapy with no emollients, 16 compared one emollient with another, 10 trials compared emollients with topical corticosteroids or calcineurin inhibitors, and two trials compared emollients with other active eczema treatments.
- There is some evidence to suggest that emollients may be steroid sparing and that they can be useful in the prevention of eczema flares.
- The paucity of good clinical trial evidence does not reflect the importance of emollient therapy for the treatment of atopic eczema.

**Do topical steroids help?****Efficacy**

**Versus placebo** The effectiveness of topical corticosteroids in comparison with placebo has been demonstrated in one systematic review (search date 1999, 13 RCTs) [49] and nine further RCTs [76,88–94] comparing topical steroids with placebo (vehicle) applied for up to 6 weeks in patients with atopic eczema (Web Table 24.2). Nineteen studies found significant improvement with topical steroid in comparison with placebo [76,89–104]. Hebert *et al.* and Lebwohl each include two RCTs [94,102] (Web Table 24.1). The three remaining studies were unable to demonstrate a significant difference between steroid and placebo [88,105,106]. No long-term studies were identified.

**Versus each other** One systematic review (including 40 RCTs) [49] and four further RCTs (including 539 patients) were identified that compare a variety of topical steroids with each other (Kirkup *et al.* [107] include two RCTs) [76,107,108]. These studies showed significant improvements in 13–100% of patients after 1–12 weeks of treatment.

**Versus topical tacrolimus and pimecrolimus** This is discussed in later sections of this chapter.

**Prevention of relapse** Five RCTs have demonstrated that intermittent treatment with a potent topical steroid can reduce the number of flare-ups of atopic eczema [78,109–112]. In the first three RCTs, adults ( $n = 430$ ) or children aged 4–10 years ( $n = 90$ ) with atopic eczema were stabilized with a 4-week course of a potent topical steroid (fluticasone propionate), followed by subsequent application of the steroid on two consecutive days a week for 16 weeks. “Weekend” steroid therapy was significantly more effective in maintaining an improvement in comparison with placebo [109,110,112]. In the fourth RCT (including 372 adults and children), patients were stabilized with a 4-week course of fluticasone propionate followed by subsequent application on 4 days a week for 4 weeks and then on two consecutive days a week for 16 weeks, again showing a significant reduction in the relapse rate in comparison with placebo [111]. In the fifth RCT patients  $\geq 12$  years ( $n = 249$ ) with atopic eczema were stabilized with a 4-week course of a potent topical steroid (methylprednisolone aceponate 0.1%), followed by subsequent application of the steroid on two consecutive days a week for 16 weeks. “Weekend” steroid therapy was again found to be significantly more effective in maintaining an improvement in comparison with placebo [78]. No direct comparisons of relapse prevention by using topical corticosteroids compared with topical tacrolimus or pimecrolimus have been made, although a systematic

review of both treatments used in such a proactive way suggested a larger benefit from topical corticosteroids [41].

**Application under wet wraps** Three RCTs [113–115] and two further small randomized within-patient comparison studies [116,117] have examined the use of wet-wrap bandaging (wet cotton tubular dressings) applied over topical steroids. In the first RCT, 40 children (aged 1–15 years) with moderate to severe eczema were treated once daily with either one-tenth strength mometasone furoate 0.005% ointment or one-tenth strength fluticasone propionate 0.005% ointment unoccluded for 2 weeks, and then randomly assigned to receive the same treatment with or without wet-wrap bandaging for a further 2 weeks. Patients treated with wet wraps finished the study with significantly less extensive and less severe disease, and with a significant improvement in subjective scores [113]. In the second RCT, 50 infants (aged 4–27 months) with moderate to severe eczema were treated with emollients and 1% hydrocortisone, with or without additional wet-wrap bandages, for 4 weeks. In both groups, there was a greater than 50% improvement in the overall eczema score (SCORAD), with no statistically significant differences between the two groups, although the group receiving wet wraps suffered more skin infections [114]. The third RCT was a small randomized controlled pilot study (19 infants <5 years), which found no benefit with 1% hydrocortisone plus wet wraps versus 1% hydrocortisone alone after 2 weeks [115]. In the first within-patient comparison study, 20 children (aged 2–17 years) were treated with twice-daily wet wraps over 0.1% mometasone furoate or vehicle for 5 days (left–right design), with a statistically significant improvement in the side treated with steroid plus wet wraps versus vehicle plus wet wraps [116]. In the second within-patient comparison study, 24 adults and children with an acute exacerbation of eczema were treated with prednicarbate with or without wet wraps (left–right design) for up to 3 days. This study showed a significantly greater improvement on the side treated with topical steroid and wet wraps in comparison with topical steroid alone [117].

A recent critical literature review of the use of wet wraps in children includes nine additional observational studies on the use of wet-wrap dressings in children with atopic eczema; it concluded that large prospective RCTs evaluating wet wraps are lacking [118].

**Frequency of application**

One systematic review (including 10 RCTs and one earlier systematic review [49]), and two further RCTs [92,119] have addressed this issue [120]. These studies found no clear evidence to support twice-daily over once-daily administration of topical corticosteroids, suggesting once-daily treatment as a first step in all patients with atopic eczema.

**Pulsed or continuous treatment**

One RCT (207 children with mild to moderate atopic dermatitis, aged 1–15 years) has compared 3-day bursts of a potent topical steroid (betamethasone valerate 0.1% ointment) followed by a 4-day rest period versus continuous use of a mild preparation (hydrocortisone 1% ointment) for 7 days. Participants used the preparations as required over an 18-week trial period. No significant differences in patient symptoms or clinical disease severity were demonstrated between the two treatment groups [121]. Another RCT study including 40 children (published in abstract form) concluded that pulsed clobetasone butyrate 0.05% is more effective than continuous treatment [122].

### Drawbacks

No serious systemic effects or cases of skin atrophy were reported in the short-term RCTs described above. Minor adverse effects such as burning, stinging, irritation, folliculitis, hypertrichosis, contact dermatitis, and changes in skin pigmentation occurred in less than 10% of patients. No cases of skin atrophy were seen in two longer RCTs (of 20 weeks' and 18 weeks' duration) using histological examination and pulsed ultrasound, respectively [109,121]. No visible signs of skin atrophy were detected in RCTs of children and adults after 4 weeks of twice-daily potent topical steroid followed by intermittent application for 12–20 weeks [78,107,111,112]. In a further RCT including 376 adults, one patient developed visible signs of skin atrophy (telangiectasia) during 4 weeks of daily potent topical steroid treatment [110]. No serious systemic effects or cases of skin atrophy were reported with regular topical steroids of mild to moderate potency in a longer cohort study in 14 prepubertal children (median treatment period 6.5 years) [123]. Temporary suppression of the hypothalamic–pituitary–adrenal axis is uncommon [119]. Enhanced topical steroid absorption and temporary suppression of the hypothalamic–pituitary–adrenal axis have been demonstrated with wet-wrap dressings in patients with severe widespread eczema [118].

Four very small RCTs in healthy volunteers (12 adults) have used ultrasound to evaluate skin thickness after topical steroid application [124–127]. Significant skin thinning occurred after 1 week with twice-daily 0.05% clobetasol 17-propionate and after 3 weeks with twice-daily 0.1% triamcinolone acetate and 0.1% betamethasone 17-valerate. All preparations were used for up to 6 weeks, and skin thinning reversed within 4 weeks of stopping treatment. No significant thinning was reported with twice-daily hydrocortisone prednicarbate or once-daily mometasone furoate after 6 weeks. One systematic review of adverse effects of topical treatments for atopic eczema concluded that physiological side effects are uncommon and systemic effects are rare [128].

### Comments

The majority of trials of topical steroids for atopic eczema have been of short duration, even though atopic eczema is a chronic relapsing disease in which topical steroids may be required for months or years. Trials that have examined the potential benefit of weekly topical steroids for preventing eczema flares have suggested large benefits. Trials have used a wide variety of clinical scoring systems, making it difficult to compare results, and many trials have studied adults only. It is not possible to recommend a “best” topical steroid, as most trials have only compared one against another, but seldom against the same one and never all together. In the only trial comparing short bursts of potent steroid versus a longer duration of mild topical steroids, the majority of patients were recruited from primary care and had mild eczema only. Further trials involving patients with more severe disease are needed in order to define the most effective method of using topical steroids in the long-term management of the disease and prevention of relapse. It is also unclear how long an initial stabilization period needs to be in order to enjoy better subsequent long-term control. The majority of RCTs have not specifically addressed skin atrophy and have been of too short a duration to adequately assess risk with long-term use of topical steroids. The clinical significance of skin thinning, as detected by statistically significant changes in total skin thickness when measured by ultrasound, is unclear, especially as the whole point of treating thickened lichenified eczematous skin is to restore it to its normal thickness and appearance. Only one RCT has addressed the

risks of skin atrophy in children objectively using ultrasound [121], and further trials using a range of topical steroids of different strengths are needed in order to guide safe prescribing.

### Implications for practice

Although topical steroids have been used for the treatment of atopic eczema for over 40 years, surprisingly little work has been done to understand how best to use them for the long-term control of atopic eczema. Most RCTs have compared “me-too” products in studies lasting only a few weeks, instead of addressing important questions such as the optimum duration of application and whether one should use short bursts of potent steroids followed by milder preparations, or vice versa. The short-term studies have failed to evaluate the speed of onset of one type of steroid in comparison with another – an important consideration when trying to control the symptoms quickly in the child depicted in the case scenario. Despite widespread concern about skin thinning with topical steroids, which has arisen from occasional horror stories of people using very potent preparations continuously at sensitive sites such as the face or groin area for inappropriate periods, RCT evidence does not suggest that clinically significant skin thinning is a problem.

In relation to the child portrayed in the case scenario, a possible evidence-based treatment approach could involve the use of a potent topical steroid (for example, an inexpensive preparation such as betamethasone valerate once daily) for 2–4 weeks to gain remission, followed by emollient-only “steroid holidays” to allow any skin thinning to recover. Future flares could then be treated with 3-day bursts of the same potent preparation. If this should fail to achieve sufficient overall control in terms of frequency and duration of remission, another approach would be to use the same preparation every weekend on active and previously healed sites.

### Key points: topical steroids

- Older RCTs of topical steroids versus placebo suggest a large treatment effect in atopic eczema.
- It is not possible to make recommendations about the “best” topical steroid, as no RCT has compared all the available preparations of similar potency.
- There is no clear RCT evidence to support the use of twice-daily over once-daily topical steroid administration.
- There is good RCT evidence that application of twice-weekly potent topical steroid to stabilized eczema can reduce the number of flare-ups in adults and children, although further RCTs are needed to confirm the long-term safety profile of this approach in infants.
- There is no RCT evidence that skin thinning is a problem with correct use of topical steroids, although most RCTs have been of short duration and other non-RCT evidence should be considered before firm conclusions are drawn.

### Do oral antihistamines help?

Only oral antihistamine agents are considered here. For the purposes of answering the question, we have included studies whose outcome measures were global indices such as quality of life (which may actually be enhanced in the context of a sedative drug used nocturnally, but is normally decreased in conventional studies, where daytime sedation is a side effect). We also considered trials in which specific indices such as disease severity scores or itch assessments were assessed irrespective of the systemic side-effect profile.

### Efficacy

One systematic review was identified, 21 RCTs, and two subsequent RCTs. The studies are summarized in Web Table 24.3 [129–152]. Tabulation and systematic analysis of these trials revealed no clear or powerful effect of administering antihistamines to children or adults. Seven of the trials used physician-assessed global severity and five used patient-assessed global severity. The most commonly reported outcome was patient-assessed itch. The largest and longest clinical trial to date (conducted over 18 months) found no significant difference in atopic eczema severity, as measured using SCORAD, when cetirizine (a nonsedating antihistamine) was compared with placebo [150]. Another subsequent study suggests that chlorpheniramine (a sedating antihistamine) may help reduce the duration and amount of moderate to strong topical corticosteroid use [151].

### Comments

The lack of emergent clarity in these trials reflects the way many dermatology studies are powered: low patient numbers in trials intrinsically demand large treatment effects to be statistically significant. It is therefore likely, from an intuitive point of view, that no large effects will be derived from the use of antihistamines, as the everyday experience of dermatologists will already attest. The individual merits of antihistamine treatments cannot be covered by such a review; and in particular, the patient-specificity of drug effects is necessarily lost when considering aggregated cohorts and statistical means, not to mention the differences in “utility” that occur for the same drug in differing contexts. The impact of a specific context of drug administration is nowhere better seen than when comparing the sedative and nonsedative antihistamines across daytime and nighttime administrations.

### Implications for practice

Collectively, RCTs conducted to date fail to show convincing evidence of a clear benefit for oral antihistamines, regardless of whether sedative or nonsedating treatments are used. An ongoing systematic review of these trials conducted by individuals within the Cochrane Skin Group may reveal more precise conclusions if data from similar studies can be combined. In relation to the child described in the case scenario, we would not recommend the use of oral antihistamines except for very occasional use as a sedative (in which case other sedatives might be just as good).

#### Key points: oral antihistamines

- Oral antihistamines have been extensively studied.
- Over 20 RCTs on antihistamines for atopic eczema have been conducted to date, with no clear evidence of benefit, especially in the largest and longest study.
- The individuality of effect of an antihistamine on any one person or given situation is variable enough to allow us to ignore pooled studies and to go on to recommend antihistamines in those contexts, or for those patients, where a potential benefit is obvious or already noted by either the patient, physician, or carer.

### What about topical tacrolimus?

Tacrolimus is a powerful immunosuppressant drug used to prevent the rejection of organ transplants. Chemically, it is a macrolide lactone isolated from the bacterium *Streptomyces tsukubaensis*. A topical form of tacrolimus (FK-506) was developed to treat atopic eczema. Topical tacrolimus is thought to benefit atopic eczema by

inhibiting phosphatase activity of calcineurin and thereby the dephosphorylation of the nuclear factor for activated T-cell protein, which is necessary for the expression of inflammatory cytokines. Downregulation of the high-affinity IgE receptor on Langerhans cells and inhibition of release of inflammatory mediators from mast cells and basophils may also partly explain the beneficial effect of tacrolimus in atopic eczema [153,154].

### Efficacy

The systematic reviews highlighted in the last edition of this textbook [49,155] have been superseded by a flurry of nine further systematic reviews dealing with different aspects of topical tacrolimus or pimecrolimus which will be discussed in the next section. The systematic reviews may all be found on the Centre of Evidence-Based Dermatology map of systematic reviews of eczema (<http://nottingham.ac.uk/research/groups/cebd/resources/index.aspx>) and additional reviews will be added to that resource as they become available. All of the placebo-controlled trials show that topical tacrolimus (0.1% and 0.03%) works better than placebo at 12 weeks. Further trials have compared 0.03% tacrolimus versus 0.1% tacrolimus, and not surprisingly these suggest that the stronger preparation is more effective than the weaker one at 12 weeks. Such placebo-controlled studies add little to clinical decision-making. The most relevant comparators for topical tacrolimus are moderate and potent topical corticosteroids. A well-conducted systematic review in 2011 found 17 trials comparing topical corticosteroids with topical tacrolimus 0.1% or 0.03% and showed in general that tacrolimus had similar efficacy to mild to moderate corticosteroids [156]. A further six trials compared tacrolimus with potent corticosteroids. Four of these trials showed tacrolimus 0.1% to be less effective or equivalent to fluticasone (potent steroid). Another systematic review conducted in 2011, which looks virtually identical to another published the following year by the same team [157,158], looked specifically at the comparative efficacy of topical tacrolimus versus topical pimecrolimus and included four RCTs of 1834 patients with varying degrees of severity of atopic eczema and concluded that topical tacrolimus had greater efficacy than topical pimecrolimus. Specifically, they found that 0.1% tacrolimus was more effective at 6 weeks than 1% pimecrolimus in adults (relative risk [RR] of failure, 0.58; 95% CI; 0.46–0.72) and children (RR, 0.55; 95% CI, 0.34–0.88) with moderate to severe atopic eczema. They also found that fewer pediatric patients withdrew from trials due to lack of efficacy or adverse events in those using 0.03% tacrolimus compared with 1% pimecrolimus, although there was no clear difference in efficacy between the two for children with mild to moderate eczema.

Since eczema is typically a long-term condition with frequent flares, topical tacrolimus has been used in a similar way to potent topical corticosteroids for two consecutive days each week following initial stabilization in the hope of trying to reduce the frequency of future flares. The use of topical tacrolimus in such a proactive rather than reactive way was systematically reviewed by Schmitt *et al.* in 2011 [41]. They found eight trials that included 1768 patients with moderate to severe atopic eczema, three of which compared 2–3 days per week of tacrolimus ointment vehicle, and five of which compared potent topical corticosteroids (fluticasone propionate in four studies and methylprednisolone aceponate 0.1% in one study) with vehicle. Both topical tacrolimus and topical corticosteroids reduced flares by around half when compared with vehicle (for fluticasone propionate: RR, 0.46; 95% CI, 0.38–0.55; for tacrolimus ointment: RR, 0.78; 95% CI, 0.60–1.00). No head-to-head studies of topical tacrolimus versus topical corticosteroids

have been done, but the meta-analysis above suggests a slightly greater effect for topical corticosteroids, which is also probably less expensive [159].

### Drawbacks

The RCTs and various safety studies published to date suggest that topical tacrolimus is a safe drug, at least in the short term. Very little of the drug is absorbed systemically. Transient burning at the site of application is a common phenomenon, occurring in about half of adults. Skin burning with 0.1% tacrolimus is about three times commoner than with 0.03% tacrolimus or moderate-potency topical corticosteroids [156]. Local irritation increases to 80% for 0.1% tacrolimus when applied to the head and neck area [160]. Topical irritation may be diminished with simultaneous application of a topical corticosteroid [161]. Apart from case reports, which are prone to selection bias, there is no clear evidence of an increased risk of skin or internal malignancy such as lymphoma with topical tacrolimus [128,155,162,163]. There is almost complete absence of data reported on clinically significant skin thinning or adrenal gland suppression.

### Comments

There is little doubt that topical tacrolimus is an effective drug for atopic eczema in comparison with vehicle, with some gains in efficacy for the stronger 0.1% preparation. The drug appears to be safe in the short term, although it should be borne in mind that tacrolimus is a potent immunosuppressive, and more data will be needed on skin infections such as herpes simplex and eczema herpeticum. Longer term surveillance data using validated databases will also be needed on the subsequent risk of internal malignancies such as lymphoma. Given that topical tacrolimus is likely to be applied frequently to facial skin – a frequent site for atopic eczema involvement – there is a need to carefully evaluate the risk of excess skin cancer on areas of the skin exposed to the sun.

It is always helpful to have a few alternatives for treating a chronic disease like eczema. What is less clear for the practicing physician is where exactly topical tacrolimus fits in with the other currently available therapies, such as topical corticosteroids [164].

Studies summarized in the systematic review suggest that 0.1% topical tacrolimus is superior to weak topical corticosteroids, but probably less effective than potent topical corticosteroids [155]. Some have suggested that topical calcineurin inhibitors can be used with topical corticosteroids either simultaneously (at the same or different body sites) or sequentially, but the evidence base in terms of efficacy and drawbacks of such an approach is still sparse [165,166].

Topical tacrolimus has been licensed in the USA and UK for the treatment of people with moderate to severe atopic eczema that is not adequately responsive, or who are intolerant of conventional therapies. Yet – rather oddly, however – none of the RCTs has been conducted specifically in people in whom topical steroids have failed. In other words, the evidence base is completely absent for the very group of people in whom it is recommended for use. This raises the question of why product licenses were granted for such second-line use, given the lack of relevant evidence to inform such a decision. The percentage of atopic eczema sufferers who are truly “unresponsive” to topical steroids is probably very small (around 10% of patients with severe cases seen in secondary care) [167]. It is likely, therefore, that the drug will be used in a much wider group of topic eczema patients as an alternative to topical corticosteroids – a prediction that is likely to be fulfilled, given existing widespread and often unjustified public fear of using topical steroids [168].

The lack of skin thinning with prolonged use of topical tacrolimus is a distinct advantage over topical steroids when the latter have to be used in excessive quantities for sites that are prone to skin thinning, such as the face. Even so, clinically significant skin thinning with intermittent use of topical steroids is rare in modern clinical practice [169], and it is odd that none of the trials to date has demonstrated a clear reduction in clinically noticeable skin thinning with topical tacrolimus in comparison with optimum use of topical corticosteroids – given that lack of skin thinning is one of its main selling points [170]. Some case series have suggested that there is a good response of facial atopic eczema and atopic blepharitis to topical tacrolimus [171–173], and these may be two scenarios in which the drug will prove to be particularly useful.

One detailed cost-effectiveness technology appraisal using Markov modeling of chronic eczema conducted for the UK Health Technology Assessment Programme in 2005 found wide uncertainty in estimating the cost effectiveness of tacrolimus in comparison with standard treatment [174], although another cost-effectiveness study from Sweden suggested that topical tacrolimus was cost effective in comparison with standard therapy [175]. The use of topical tacrolimus to prevent eczema flares is supported by good evidence, but such a proactive effect has already been demonstrated for potent topical corticosteroids [41].

### Implications for clinical practice

Given the lack of crucial comparisons surrounding the introduction of topical tacrolimus, physicians and patients are still probably guessing as to how and when it should be used. The lack of a skin thinning effect may point to it being particularly useful when patients with moderate to severe disease are “stuck” on their topical steroid preparations and have to use such preparations almost continuously. Topical tacrolimus may be particularly useful for resistant facial atopic eczema, for similar reasons. Physicians should resist using such a preparation as a “steroid alternative” until more relevant RCT and safety data become available.

#### Key points: topical tacrolimus

- It is good to have additional effective topical treatments for people with moderate to severe atopic eczema.
- Topical tacrolimus (0.03% and 0.1%) works much better than vehicle only.
- Topical tacrolimus 0.1% and 0.03% has been shown to be superior to a very weak topical corticosteroid (1% hydrocortisone) in children with moderate to severe atopic eczema.
- Topical tacrolimus 0.1% is probably less effective than potent topical corticosteroids.
- Topical tacrolimus can be used for 2–3 days each week to prevent flares in those with initially stabilized eczema, but it is possibly not as effective as topical fluticasone when used in such a proactive way.
- Topical tacrolimus appears to be safe in the short term.
- Transient burning occurs in about half of adults, and is more common than with topical corticosteroids.
- Long-term data are needed on local and systemic infection, skin cancer rates, and internal cancers such as lymphoma.
- Paradoxically, none of the studies to date has tested topical tacrolimus for its suggested use as a second-line treatment for atopic eczema.
- In relation to the child described in the case scenario, we would use topical tacrolimus only when standard therapy with short bursts of once-daily potent topical steroids (or very mild preparations for the face), emollients, and educational support had failed.

### How might topical pimecrolimus be used?

Like tacrolimus, pimecrolimus is a macrolide immunosuppressive drug [176]. It is currently available in many countries worldwide for “short-term intermittent long-term therapy in the treatment of *mild to moderate* atopic dermatitis in non-immunocompromised patients 2 years of age and older, in whom the use of alternative, conventional therapies is deemed inadvisable because of potential risks, or in the treatment of patients who are not adequately responsive to or are intolerant to conventional therapies” [177]. The primary indication of use is almost identical to that described for topical tacrolimus, except that pimecrolimus is aimed at mild to moderate atopic dermatitis whereas tacrolimus is aimed at moderate to severe atopic dermatitis. Given that mild atopic eczema is about 10 times more frequent than moderate to severe disease [18], the market could be a lot larger for pimecrolimus. Pimecrolimus has also been used to prevent disease flares.

The mode of action of pimecrolimus is thought to be similar to that of tacrolimus and ciclosporin in preventing the release of calcineurin-mediated cytokine and proinflammatory mediators from mast cells and T cells [154].

### Efficacy

A Cochrane systematic review conducted in 2007 included 31 trials of 8019 participants showed that pimecrolimus was significantly more effective than vehicle (the cream base not containing pimecrolimus) in the short term [178]. That review also found nine RCTs of preventing flares in 3091 participants over a 6-month period, a finding confirmed in another systematic review [179]. The Cochrane review also found that topical pimecrolimus was significantly better than vehicle in preventing flares (at 6 months: RR, 1.47; 95% CI, 1.32–1.64) and with better quality of life in the intervention group. No direct comparisons between pimecrolimus and tacrolimus for preventing flares could be found. Pimecrolimus was less effective than topical corticosteroids, but too few studies had been done at that time to comment on a direct comparison with topical tacrolimus. A subsequent systematic review in 2011 undertook a meta-analysis of four RCTs of 1843 participants which had compared topical pimecrolimus against tacrolimus and found that 0.1% tacrolimus was more effective than 1% pimecrolimus for adults (RR, 0.58; 95% CI, 0.46–0.72) and children with severe eczema (RR, 0.55; 95% CI, 0.34–0.88) at week 6 [157]. There was no significant difference between 1% pimecrolimus and 0.03% tacrolimus in children with mild to moderate atopic eczema, but this was only based on two short-term studies, and the confidence intervals around these estimates were wide. One study has explored the value of topical pimecrolimus for children who are intolerant of or who have become dependent on topical corticosteroids for facial eczema [180]. Not surprisingly, topical pimecrolimus was shown to be better than vehicle alone. Another study of 376 children tried to evaluate whether addition of 1% pimecrolimus to fluticasone conferred additional benefit, and although the addition of pimecrolimus did not seem to increase adverse effects, no clinical benefit in eczema severity or time to clearance was noted [181].

### Drawbacks

Data from RCTs do not suggest any serious adverse effects to date [174,178]. Application reactions of burning, warmth, stinging, and soreness have been consistently reported in the RCTs and are dose related. Pimecrolimus 1% skin irritation and burning was not significantly different from vehicle in the 2005 systematic review (pooled rate from six trials, 0.87; 95% CI, 0.70–1.09), but skin

burning was higher with pimecrolimus than with topical corticosteroids [174]. The systematic review did not show any increase in skin infections with pimecrolimus 1%. Adverse events such as burning and itching were about the same in the two systematic reviews conducted in 2010 and 2011 [157,179]. Skin thinning does not seem to occur with topical pimecrolimus, whereas mild topical corticosteroids can result in transient skin thinning on the face, the clinical relevance of which is unclear [170]. Systemic absorption does occur with pimecrolimus, but this is very small in the majority of people [182,183]. No skin atrophy has been observed in a detailed study comparing topical pimecrolimus with 0.1% betamethasone valerate cream when applied to the forearms of healthy volunteers continuously for 4 weeks [184]. However, this type of study is difficult to interpret, as potent topical steroids are not used in this way and the effects of disease on skin thickness cannot be assessed.

As pimecrolimus is an immunosuppressive agent, the theoretical long-term risk of cancer needs to be monitored [163,185], given that the drug is likely to be prescribed in large quantities to millions of children with mild forms of this common disease.

### Comments

The quality of reporting in the pimecrolimus studies was generally good. There is no doubt from the many vehicle-controlled studies that pimecrolimus is effective in treating atopic eczema in terms of reducing symptoms, improving physical signs of eczema, and improving the quality of life. Yet despite the profusion of vehicle-controlled studies (which some might consider unethical, given that several early studies established efficacy) [186], numerous open-label studies, and consensus statements produced by physicians with conflicts of interest, the key comparisons between pimecrolimus and current commonly used treatments for mild to moderate conditions – that is, mild to moderate topical corticosteroids – appear to be completely missing. The early study that compared pimecrolimus with betamethasone showed that betamethasone was much more effective, and adding pimecrolimus to topical corticosteroids did not confer any gains. Some studies suggest that topical pimecrolimus might be useful in people who are intolerant of topical corticosteroids or who become dependent on them. Terms such as “intolerance” or “dependency,” although reasonably defined in some study protocols [180], have a wide possible interpretation and could include many who are simply anxious about using topical corticosteroids. Some atopic eczema patients do become “addicted” to inappropriate use of topical corticosteroids [187], especially on the face, and these patients might well benefit from topical pimecrolimus or tacrolimus. The studies that evaluated the use of pimecrolimus applied at the first sign of a flare to reduce the flare severity and frequency appear interesting (and at least they address the chronic relapsing nature of atopic eczema [49]) – until, that is, one realizes that they are effectively placebo-controlled studies. It could have been the case that early treatment with very mild and safe 1% hydrocortisone acetate ointment would have averted the development of flares equally well. Others have pointed out that it is normal to wait until a flare becomes moderate to severe before initiating treatment with a topical corticosteroid, and in that sense the prevention-of-flare studies are somewhat unrealistic [188]. As a result of missing studies, the physician and patient are left guessing about how pimecrolimus compares with the best standard therapy [189].

One detailed economic assessment concluded that there was too much uncertainty in assessing the cost effectiveness of pimecrolimus [174], although a later study suggested that pimecrolimus

was cost effective in comparison with standard therapy in a US setting [190]. Previous technology appraisals on pimecrolimus and tacrolimus by the UK National Institute of Health and Clinical Excellence have resulted in both being included as second-line treatments for atopic eczema in children [52].

### Implications for practice

In relation to the child described in the case scenario, the lack of key comparisons in published trials makes it difficult to decide with the child's parents when and how to use topical pimecrolimus. We would consider pimecrolimus if the child needed to use potent topical steroids almost continuously in order to obtain a reasonable quality of life, although we would not be too optimistic about the ability of pimecrolimus to work where potent topical corticosteroids had failed. We might use topical pimecrolimus for persistent sensitive-site eczema (such as on the face) if topical corticosteroids or topical 0.03% tacrolimus had failed or caused too much burning or stinging. We would also consider trying pimecrolimus if the child's parents were letting the child suffer terribly from uncontrolled eczema because of an irrational fear of using any form of topical steroids, although we would probably use tacrolimus 0.1% first. We would also consider trying topical pimecrolimus to prevent flares in children with brittle disease if prevention of flares with topical corticosteroids or topical tacrolimus was ineffective.

### Key points: topical pimecrolimus

- Pimecrolimus 1% cream works better than vehicle cream in children and adults with mild to moderate atopic eczema. There is no need for any more vehicle-controlled studies of pimecrolimus.
- Like topical tacrolimus, pimecrolimus 1% could be useful for eczema in sensitive sites such as the face if topical corticosteroid use is no longer effective or use is excessive.
- Topical pimecrolimus is probably less effective than tacrolimus.
- Topical 1% pimecrolimus cream is much less effective than topical betamethasone valerate in atopic eczema.
- Pimecrolimus 1% has not been compared with 1% hydrocortisone or other mild to moderate topical corticosteroids for short-term or long-term treatment for reasons that are unclear.
- Some evidence supports the notion that pimecrolimus is better than vehicle in people who have adverse effects from topical corticosteroids.
- Topical 1% pimecrolimus does not cause skin thinning.
- Local application-site reactions such as burning are common, mild, and transient.
- Topical pimecrolimus appears to be safe in the short term, although its long-term safety is unknown.
- It is not known whether early treatment with topical pimecrolimus is any better than early treatment with a weak topical steroid such as 1% hydrocortisone or 0.03% topical tacrolimus in preventing disease flares.
- Independent studies are needed in order to compare the cost effectiveness of pimecrolimus with standard bursts of mild to moderate topical steroids in the short-term control of mild atopic eczema in children, and to see whether early use of either treatment approach improves disease control over a longer period.

### Will interventions to reduce house dust mite improve this child's eczema?

#### Efficacy

This section deals with house dust mite eradication for cases of established atopic eczema. No systematic review was found

for house dust mite reduction in atopic eczema. However, a recent Cochrane systematic review of house dust mite reduction for the treatment of asthma reported no improvement in the symptoms of asthma [191]. The authors concluded that "It is doubtful whether further studies, similar to the ones in our meta-analysis, are worthwhile."

Seven RCTs [192–198] evaluating the role of house dust mite reduction in the treatment of *established* atopic eczema were identified and are summarized in Web Table 24.4. Trials were excluded if they looked at the prevention of atopic eczema in newborn children (for example, Koopman *et al.* [199] and Horak *et al.* [200]), because the results were not presented for atopic eczema in a disaggregated form (for example, Terreehorst *et al.* [201]), or because data were not presented on the clinical impact of the interventions (for example, Nishioka *et al.* [202]). In general, the evidence to support the efficacy of house dust mite eradication for the treatment of atopic eczema is of poor quality. Interventions such as vacuuming and the use of synthetic mattress covers appear to be most effective in reducing the house dust mite load, but how this impacts on disease severity is still unclear.

The first small RCT by Colloff *et al.* [192] evaluated the daily use of natamycin (a spray used to kill house dust mites) versus a matched placebo spray with and without vacuum cleaning in a parallel-group study for 4 months in 20 young adults with atopic eczema. The authors demonstrated that it was the vacuum cleaning and not the natamycin spray that had a significant impact on reducing house dust mite numbers. There was no significant clinical improvement in those who had been allocated to natamycin versus placebo. The mean symptom score (maximum score 288) in the natamycin and vacuum group changed from 55.2 at baseline to 38.6 at 4 months, in comparison with 45.2 to 35.8 in the group with no natamycin and no daily vacuuming.

A second small, but important, RCT was conducted by Tan *et al.* in 1996 [193], with duplicated publication in 1998 and again in 1999. Tan *et al.* randomly assigned 60 patients (30 adults and 30 children) for a total of 6 months to an intensive dust mite eradication regimen involving Gore-Tex (Intervent, UK) bedding covers, benzyl tannate spray to kill mites and denature their allergens, and a high-filtration vacuum cleaner, or to a control group with plain cotton bedcovers, placebo spray, and a standard upright vacuum cleaner with poor filtration performance. One trained nurse applied the bedcovers and spray each week, and participants were encouraged to vacuum their bedrooms daily. There was a dramatic and very similar reduction in the concentration of house dust mite major allergen (*Der p1*) in bedroom carpets in both the active and placebo treatment groups at the end of 6 months. Disease activity – as recorded in terms of surface area involvement and with a composite severity score (maximum score 108) measured at one point at the end of the 6 months – was reduced by a small amount in both groups, but more so in the active group. The mean reduction in scores for the active and placebo groups were 12.6 and 4.2 units, respectively. Those in the active treatment group had more severe conditions to begin with, and so an analysis of covariance was conducted to allow for baseline scores and initial house dust mite antigen levels. This showed a mean difference of 4.2 in the change of score (95% CI, 1.7–6.7 units;  $P = 0.008$ ) between the two treatments. Further analysis also suggested that it was changes in the mattress and carpet dust in the bedroom that mediated much of the treatment effect. Subgroup analysis suggested that only children had a clinically and statistically significant benefit, and that there was no correlation between

clinical improvement and positive skin prick tests at the study outset.

Another small study in Japan by Endo *et al.* [194] evaluated the potential benefit of intensive vacuum cleaning in the rooms of 30 children with atopic eczema for a total of 12 months. Both groups were visited every 3 weeks by a team of mite specialists, who either cleaned room floors, mattresses, and quilts very thoroughly and encouraged parents to clean in the same way in between visits, or performed a less intensive clean (vacuum suction power reduced to 50%) with similar cleaning between visits. Parents were thus unblinded to the intervention. A statistically significant decrease in mite numbers in favor of the intensive cleaning group was only noted for the room floors. Clinical scores, as evaluated by a physician blind to treatment allocation, were significantly improved in the active group in comparison with baseline, but not in the control group. Clinical scores were given in graphic form only, and the appropriate statistical test of mean difference between the two treatments was not reported.

Oosting *et al.* [195] compared Gore-Tex mattress, duvet, and pillow covers with placebo covers made from cotton for a period of 12 months. Eighty-six children and adults took part, all of whom had atopic eczema and were allergic to house dust mite. Whilst the mattress covers resulted in a significant reduction in the house dust mite load, no significant between-group differences were observed in clinical features or self-reported itch and sleep loss.

The remaining studies were all very small (41 participants [196], 20 participants [197], and 43 participants [198]), making conclusions difficult.

### Drawbacks

None of the studies reported any adverse events of the house dust mite removal treatments. This does not necessarily imply that none occurred. The imposition of daily vacuuming for a long period has a cost in terms of time for parents and sufferers, as does the purchase of a high-filtration vacuum cleaner, impermeable mattress covers, and mite sprays.

### Comments

Given the strong circumstantial evidence to suggest that house dust mite allergens may play a part in atopic eczema, it is a pity that so few studies on house dust mite avoidance have been performed. Those that have been done tend to be small, and it is difficult to generalize in the absence of more pragmatic studies. The method of randomization and concealment was not reported adequately in any of the studies, and no intention-to-treat (ITT) analyses were performed (although drop-out rates were quite low).

Further studies that separate the different interventions for reducing house dust mite are needed. It is important that such trials should be as pragmatic as possible to determine which groups respond best, which interventions are the most cost effective, and whether the laborious interventions are sustainable in less-motivated people.

### Implications for clinical practice

In the absence of strong clinical trial data to support the use of house dust mite avoidance measures, the decision as to whether the cost and effort of implementing such procedures is warranted probably lies with the individual families. In the future, specific immunotherapy with a house dust mite preparation may be possible, and early tests have shown promising results [203].

### Key points: house dust mite

- Seven randomized controlled trials have been reported, although methodological difficulties and small sample sizes limit the interpretation of the results.
- Future, large-scale pragmatic trials are needed if this issue is to be resolved.
- In the meantime, the use of allergen-impermeable mattress and pillow covers, coupled with regular vacuuming of the room, appear to be the best way of reducing house dust mite if such changes are truly beneficial.

### Will an exclusion diet (such as a milk- or egg-free diet) alone help reduce the symptoms of this child's atopic eczema?

This section deals with exclusion diets for cases of established atopic eczema. Four systematic reviews were found. Only one Cochrane review later published in *Allergy*, with a search ending in 2006, looked exclusively at exclusion diets in established atopic eczema [204,205]. This review included nine RCTs, and since then no RCTs looking at exclusion diets have been published. Two [206,207] of the remaining three reviews used the Cochrane review as their primary evidence source [205]. The nine RCTs examining the role of elimination diets in established atopic eczema are summarized in Web Table 24.5.

### Efficacy

No evidence of benefit from elimination diets was found in the trials that included unselected participants with eczema; however, there was some evidence from one trial [208] of an egg-free diet in infants with a proven specific IgE to egg of a beneficial effect. Two trials [209,210] did not find any evidence that elemental diets were beneficial for eczema compared with a standard hospital diet in adults or a pre-existing formula in children. A study of a few-foods diet [211] with whey and a few-foods diet with casein hydrolysate or a normal diet found no beneficial effects from either of the few-food diets.

### Drawbacks

Calcium, protein, and calorie deficiency are risks associated with the use of dairy-free diets in children. Such diets should only be used under medical supervision. Three RCTs used soya-based milk substitute, which itself can be allergenic in atopic eczema.

### Comments

Methodological difficulties mean that interpretation of these trials is difficult. RCTs that employ a parallel design with an unblinded normal control diet may introduce bias in favor of the active group. In addition, those trials that place all participants on exclusion diets and then reintroduce the suspected offending food, in comparison with a control, risk introducing another allergen (for example, soya) or introducing the suspected allergen (for example, cows' milk) in a way that does not mimic real life. Poor concealment of randomization allocation, lack of blinding, and high drop-out rates without an ITT analysis all mean that the above studies should be interpreted with great caution. Future studies should ideally be longer term and more pragmatic and should ensure that randomization is concealed.

Uncontrolled elimination diets followed by double-blind, placebo-controlled challenges with foods suspected to aggravate symptoms have also been tried in atopic eczema [212–216]. These studies are not the same as RCTs of food elimination. Instead, they try to answer the question: “Does food X make a particular child’s atopic eczema worse?” The precise relationship between such food challenge studies and long-term benefits of exclusion of the suspected foods to atopic eczema sufferers is not clear. Blood and skin-prick tests are usually only helpful in predicting clinical response if they are negative [217,218]. It should also be borne in mind that a high negative predictive value has only been shown in relation to the provocation of symptoms after a double-blind challenge, and not the clinical response following food elimination, which is not necessarily the same thing. The relationship between atopic eczema and food sensitivity is a complex one, and readers are referred to a clear evidence-based work by David for further information [219].

### Implications for clinical practice

Elimination diets are difficult for families and patients to follow, even in the highly motivated environment of a clinical trial. In the absence of clear evidence of the involvement of a particular food substance, the possible harms may outweigh the benefits. In cases in which exclusion diets are indicated, appropriate dietary advice and support should be made available.

#### Key points: exclusion diet

- There is little evidence to support a diet free of eggs and milk in unselected patients with atopic eczema.
- There is no evidence to support the use of an elemental or few-foods diet in atopic eczema.
- There is some evidence to support the use of an egg-free diet in infants with suspected egg allergy who have positive specific IgE to eggs.
- The most common diets used are those free of milk or eggs.
- The possible risks of impaired growth and development in children should be recognized.

### Do probiotics, prebiotics, or synbiotics help reduce the symptoms of this child’s atopic eczema?

It has been suggested that probiotics (commonly referred to as “good” bacteria that have the ability to modify immune responses) and prebiotics (substances which have been shown to assist the growth of “good” bacteria) or a combination of these (“synbiotics”) might help prevent and treat atopic eczema by way of altering the intestinal microflora [220].

This section deals with probiotics used to help reduce the symptoms of atopic eczema. Three systematic reviews [221–224] were found, all published in 2008, with the most up to date being a Cochrane review, also published in *Clinical and Experimental Allergy*, with a search ending April 2008. The Cochrane review and the two other reviews all included the same 12 RCTs [220,225–235]. One review also included an additional RCT looking at the effects of probiotics on levels of polyunsaturated fatty acids, but no clinical outcomes. Including the trials published since the Cochrane review, a total of 27 RCTs have so far evaluated the role of probiotics, prebiotics, and synbiotics in the treatment of *established* atopic eczema [220,225–250]. These are summarized in Web Table 24.6.

Seven of the 27 studies use extensively hydrolyzed formula milk to avoid cows’ milk [220,225,226,228,230,232,237].

### Efficacy

All three systematic reviews [221–224] found *no convincing evidence* that probiotics confer clinically meaningful benefit for treating established eczema. The seven trials published since then have mostly provided *evidence of no benefit* for single-strain probiotics, particularly *Lactobacillus rhamnosus*, for treating established eczema [237,240–242,244,248,249].

There is *evidence of no benefit* from three trials for mixtures of probiotic strains compared with placebo, whether or not the participants had a cows’ milk allergy or sensitization to one or more allergens [227,235,238]. These trials all found significant benefits for post hoc subgroups with raised IgE levels. The trials of lactobacilli strains of probiotics mostly do not show any significant benefits compared with placebo or in addition to standard treatments. These mostly small trials were in quite selective populations and gave little detail about which outcomes and statistical outcomes were prespecified.

Four trials compared different synbiotic combinations against inactive placebo or a placebo of hydrolyzed formula given to both groups [236,239,243,245]. Three of these trials found a significant benefit for eczema severity from synbiotics after 8 or 12 weeks [236,239,243], with one of these positive results only being found in a possibly post-hoc subgroup of IgE-associated eczema [239]. One trial [234] compared a synbiotic mixture with a prebiotic preparation alone and found no significant difference in SCORAD at the end of the study. Two trials [247,250] of prebiotics compared with placebo or no treatment were difficult to interpret, as clinically relevant between-group analyses were not reported.

The seven studies looking at elimination diets together with probiotics and synbiotics showed no significant differences in eczema severity between the treatment groups and placebo.

### Drawbacks

Around half of the trials reported information about adverse events, and although the levels of adverse events were often quite high, only a few were thought to be related to treatment. Recruitment in one study [226] was prematurely terminated due to concern over adverse gastrointestinal symptoms, which were limited to the group receiving heat-inactivated *L. rhamnosus* GG.

### Comments

The only positive results have mostly been from post hoc sub-analyses of IgE-associated “atopic” eczema, but no trial has yet prospectively assessed such a group, and so the results must be treated with caution. Most of the trials were small with little or no detail about the method of randomization, allocation concealment, blinding, and which outcomes were prespecified. Most of the trials did not analyze the results using an ITT principle, and withdrawals were often relatively high. Short-term outcomes, selective populations, and a lack of clear reporting of results all mean that probiotics may have potential for individuals from populations not studied and for longer time periods. One abstract of a trial on *Lactobacillus reuteri* seems to indicate a significant reduction in extent of eczema, sleep loss, and itching from once-a-day supplementation per day for a year [246]. There was not enough detail in the abstract to assess this trial properly. The full trial report is awaited with interest.

**Key points: probiotics, probiotics and synbiotics**

- There is little convincing evidence that probiotics produce a clinically useful effect for the treatment of atopic eczema.
- There is some evidence to suggest that a subset of patients who test positive for IgE might benefit from the use of probiotics.
- Trials are needed in these specific subsets of eczema patients before probiotic treatment can be recommended.
- Synbiotics show some weak evidence of benefit, but this is not strong enough to recommend the use of these probiotic and probiotic mixtures in clinical practice.
- There is not yet any evidence that prebiotics alone are beneficial for eczema compared with placebo or no treatment.

**Do Chinese herbal medicines improve the symptoms of atopic eczema?****Efficacy**

Chinese herbal medicines are commonly used in Asian clinical practice and are usually taken as a decoction by boiling them in water, and drinking the “tea” produced, or as external applications directly to the skin. The mode of action points towards anti-inflammatory and immunosuppressive properties by downregulating local T-cell-mediated reactions.

Seven systematic reviews have included assessment of Chinese herbal medicines for eczema [49,251–256] and 10 RCTs have been published [257–266].

**Zemaphyte** Five trials evaluated a commercial preparation of 10 traditional Chinese herbs, comprising *Ledebouriella seseloides*, *Potentilla chinensis*, *Clematis armandii*, *Rehmannia glutinosa*, *Paenia laciflora*, *Lophatherum gracile*, *Dictamnus dasycarpus*, *Tribulus terrestris*, *Glycyrrhiza glabra*, and *Schizonepeta tenuifolia* (Zemaphyte). This preparation is no longer available.

One double-blind RCT compared Zemaphyte in a decoction and a placebo comprising of a mixture of “inert” plant materials, used once daily for 8 weeks in 47 children with atopic eczema [257]. Median percentage changes in the clinical scores for erythema in comparison with baseline were 51% for Chinese herbs and 6.1% for placebo. Change in surface damage was 63.1% and 6.2% in the Chinese herb and placebo groups, respectively. A 1-year follow-up study of the children concluded that Chinese herbal medicine, in the medium term, was helpful for approximately half the children who originally took part in the RCT [267].

A similar double-blind RCT, involving 40 adult patients with atopic dermatitis, used the same intervention and similar trial methods [258]. Significant improvements were reported for blinded assessments of erythema ( $P < 0.001$ ) and surface damage ( $P < 0.001$ ) with the herbs in comparison with the placebo.

A third double-blind crossover RCT evaluated Zemaphyte in comparison with “inert plant” placebo [260]. Forty participants with atopic eczema were randomized to Zemaphyte or placebo for 8 weeks, followed by a 4-week washout period before using the alternative therapy for a further 8 weeks. This trial found no significant differences between the groups, except for lichenification at week 4.

In addition, two RCTs have evaluated Zemaphyte used as an infusion, compared with a more palatable form of freeze-dried granules [259,261]. These trials included 18 and 32 adults with moderate to severe atopic eczema, respectively [259,261]. Both

trials followed up patients for a period of 8 weeks and found no significant differences between the groups.

**PentaHerbs** This product is a five-herb concoction containing *flos loniceriae*, *herba menthae*, *cortex moutan*, *Rhizoma atractylodis*, and *cortex phellodendri*. One trial compared PentaHerbs given in capsules for 12 weeks against placebo [263]. Eighty five children and young adults from 5 to 21 years with moderate to severe eczema (SCORAD over 15) took three capsules twice a day. There were no significant differences between the groups in the severity of eczema assessed using the SCORAD scale, but quality of life (measured using CDLQI) showed a significant improvement for the PentaHerb group compared with placebo at the end of treatment ( $P = 0.008$ ) and at 4 weeks post therapy ( $P = 0.059$ ). There was also a trend towards reduced topical steroid use in the PentaHerb group compared with placebo.

**Siberian ginseng, Achillea millefolium and Lamium album** One double-blind RCT compared a herbal preparation of Siberian ginseng, *Achillea millefolium* and *Lamium album* against placebo. Both products were taken orally three times a day for 2 weeks, with follow-up for 1 year [262]. The trial included 49 participants with moderate atopic eczema. Participants were allowed to continue with established emollients and topical corticosteroid therapy. All participants experienced a fall of around 15 to 20 points in eczema severity after 2 weeks of treatment, but there was no significant difference between the groups. Daytime pruritus and sleep loss also showed no significant difference between the herbal preparation and placebo.

**Jiawei Danggui Decection** An open trial of 47 children and adults aged 12 years and over assessed the addition of Jiawei Danggui Decection to standard care of a non-sedating antihistamine (loratadine 10 mg per day) plus a potent topical corticosteroid (hydrocortisone butyrate 0.1% once a day for 4 weeks) [264]. All participants had a diagnosis of atopic eczema. The active treatment group received 250 mL Jiawei Danggui Decection in addition to standard care, but the treatment regimen was not reported. In the active treatment group, 56% (14/25) of participants showed an improvement in eczema severity (using the six-area, six-sign atopic dermatitis (SASSAD) scale) of greater than 70%, compared with 22.7% (5/22) in the standard care control group ( $P < 0.05$ ).

**Xiao-Feng-San** This product is a mixture of 13 different plant materials commonly used for the treatment of eczema in Asian clinical practice. In a double-blind RCT including 71 children with refractory atopic eczema, Xiao-Feng-San was compared with a placebo of caramel, lactose, and starch that tasted similar to the active treatment [266]. Participants were randomized at a ratio of 2:1 in favor of the active treatment group and took the treatment three times a day for 8 weeks, followed by a no-intervention follow-up phase of a further 4 weeks (12 weeks in total). Participants had eczema on more than 20% of their body surface area and had no active infection or exudation. Only 56 of the 71 participants completed the trial, but analysis was conducted on an ITT basis to account for this. The primary outcome of eczema severity using a blinded lesion score decreased significantly in the active treatment group compared with placebo at 8 weeks (reduction of 79.1 points  $\pm 5.7\%$  vs 13.5 points  $\pm 7.6\%$ ;  $P < 0.001$ ). Similar statistically significant results were also found for erythema, surface damage, pruritus, and sleep

loss at 8 weeks. All but erythema remained significant 4 weeks after the end of treatment at the 12-week assessment.

**Hochu-ekki-to** This is a traditional herbal medicine containing 10 species of medicinal plants. The product is thought to benefit patients with a delicate, easily fatigable or hypersensitive constitution known as *Kikiyu*. A multicenter, double-blind RCT included 91 patients aged 20–40 years with atopic eczema and a Kikyu constitution (as defined using a scoring questionnaire) [265]. Participants were randomized to Hochu-ekki-to taken twice daily for 24 weeks, or an inactive placebo of similar appearance, smell, and taste. All participants continued with their standard eczema treatments throughout the trial. Eighty-four participants were included in the analysis set, and of these 77 completed the 24-week treatment period. No between-group differences were observed in the mean skin severity scores at 24 weeks, although comparison of those whose skin severity score had reduced to zero at 24 weeks favored the active treatment group (19% vs 5%;  $P = 0.06$ ). Percentage change from baseline in the amount of topical medication used (following adjustment for potency of the medication) also showed a statistically significant difference in favor of the active treatment group ( $P = 0.05$ ), suggesting that Hochu-ekki-to may be a useful steroid-sparing treatment in this population, without increasing the severity of the eczema.

### Drawbacks

Many of the trials reported that the herbal remedies were unpalatable, resulting in attempts to produce alternative formulations, such as freeze-dried preparations [259,261]. The most commonly reported adverse events were nausea and diarrhea, stomach discomfort, loose bowels or flatulence, dizziness and headache, or increased visits to a general practitioner.

The potential for hepatotoxicity is a concern with Chinese herbs. However, the six studies that carried out pretreatment and post-treatment blood tests found no significant changes in blood chemistry or renal function [257,258,260,261,265,266]. One participant had a transient elevation of aspartate aminotransferase which returned to normal levels within 8 weeks after the treatment was stopped.

### Comments

All studies were randomized, but the method and concealment of allocation were rarely described and ITT analysis was only conducted in one trial [266]. It is also questionable whether the placebo plants were truly inert. Clearly, larger scale RCTs of longer duration, using comparable methods and interventions, are needed.

### Implications for clinical practice

Ten RCTs have now been conducted looking at a variety of herbal preparations, and have demonstrated mixed treatment response. Of the eight RCTs to have compared active treatments against placebo, six reported significant beneficial effects; although the two trials by Sheehan and Atherton [257,258] were not supported by a subsequent trial of the same product [260]. The most promising remedies would appear to be Xiao-Feng-San, which was found to be beneficial in the highest quality of the reported trials [266], *PentaHerbs* [263], *Jiawei Danggui Decection* [264], and Hochu-ekki-to [265].

Further research is needed to address the long-term safety implications.

### Key points: Chinese herbal medicines

- Ten randomized controlled trials of modest size are reported, including a variety of interventions.
- Lack of standardization and replication of trial results using the same herbs makes it difficult to interpret these findings.
- Further large-scale studies are needed to clarify the role of Chinese herbal remedies in the treatment of eczema.
- A number of side effects were identified, the true implications of which cannot be addressed without long-term studies.

### What are the most appropriate washing and bathing routines for patients with atopic eczema?

#### Efficacy

**Frequency of bathing** Eczema patients are often advised to take regular baths to hydrate the skin [52], but there is a lack of clarity over the best ways of doing this, and patients often ask for recommendations on the frequency and duration of bathing [268]. We found no RCT evidence on the frequency of bathing, the use of baths compared with showers, or on the most appropriate temperature of the water.

**Soaps and soap substitutes** The use of soap is discouraged in patients with eczema, with an emphasis of “complete emollient therapy” that includes the use of soap substitutes [52,53]. However, there is little guidance on what soap substitutes are most effective and how they should be used.

We found one RCT [269] that examined the use of a liquid soap (Axera) containing 12% ammonium lactate and 20% urea, compared with commercially available liquid soap of similar odor and cleaning properties. This 3-week trial included 36 children and adults with mild to moderate eczema, who were randomized 2:1 in favor of the active intervention. Participants continued with their usual eczema treatments, with the exception of other soap or emollients. Blinding of outcome assessment was unclear. After 3 weeks, significant improvements were reported compared with the control soap group in investigator-rated scaling ( $P < 0.0001$ ), skin dryness ( $P < 0.0001$ ) and redness ( $P = 0.03$ ), and in patient-reported itch ( $P < 0.0001$ ). However, it is not clear why participants were asked to refrain from using normal emollient therapy during the trial, and it is possible that these results reflect a lack of emollient therapy in the control group.

**Antiseptic wash products** The role of antiseptic soaps and antiseptic bath products has been discussed in the section on infected eczema.

**Bath additives** Bath emollients are often recommended on the grounds that they are an easy way of applying emollients to the skin; particularly for young children who may not cooperate in allowing the application of topical medications. Bath emollients have also been advocated as a way of avoiding the use of bubble bath in children with eczema, and clinical guidelines recommend their use [52,53]. One systematic review has looked specifically at the use of bath emollients in the treatment of eczema [270] and found no RCT evidence to support their use. The use of antimicrobial bath products and bleach baths are included in the section on infected eczema.

**Washing of clothes** Detergent enzymes may cause skin irritation, leading some physicians to advise patients with atopic eczema to avoid the use of such detergents in favor of alternative “nonbiological” detergents [271]. We located one RCT testing the hypothesis that enzyme-containing detergents are more likely to aggravate atopic eczema than a nonbiological detergent [272], and one that looked at the impact of using fabric softeners in adults with atopic dermatitis [273].

In the first study [271], 26 adults with mild to moderate atopic eczema (mean age 25 years) were randomly assigned in a double-blind crossover study to use either a trial detergent containing enzymes or a visually identical detergent without enzymes for 1 month. There was a 1-month wash-out period before randomization, when participants used their usual washing powder. Topical steroids were permitted during the study and were weighed. In the 25 patients who completed the trial, there was no difference between the two groups in terms of disease severity (SCORAD scores of 29 in each group; 95% CI for mean difference, 4–5). Similar results were found for the use of topical steroids, patient-reported itch, and eczema activity.

The study looking at fabric softeners [273] was a single-blind randomized trial using a left–right comparison design for a period of 12 days. Twenty volunteers with a history of atopic dermatitis were enrolled in the study (none had active lesions at the time of enrolment). In order to simulate realistic conditions of skin damage, sodium lauryl sulfate was applied to each volar forearm under occlusion 3 days before the start of the study. A control patch using water was also applied to each arm. Repetitive wash tests were performed three times a day using softened or unsoftened fabric in random order to each arm. The investigator was blinded to the fabric used at each site. Both for the control and pre-irritated skin, all measured parameters indicated that “softened” fabric was less aggressive to the skin than “unsoftened” fabric.

**Water hardness** There is epidemiological evidence suggesting a possible link between water hardness and eczema prevalence [274,275]. One large RCT [276] involving 336 children with atopic eczema randomized participants to receive an ion-exchange water softener plus normal care, compared with normal care alone for a period of 12 weeks. The trial was assessor-blind since it was not possible to blind trial participants to their treatment allocation. Emphasis was placed on objective outcome measures such as eczema severity (using the SASSAD eczema severity scale), nighttime movement/scratching (measured using accelerometers) and topical medication use. No between-group differences were reported for any of the objective outcome measures, and the primary outcome of eczema severity showed no differences between the groups, with narrow confidence intervals (mean difference, 0.66 points; 95% CI, –1.37 to 2.69;  $P = 0.53$ ). Statistically significant differences were seen between the active and the control group in subjective outcome measures, including self-reported symptoms, quality of life, and well-controlled weeks. However, these results are likely to be subject to considerable expectation bias, and the magnitude of effect was small, suggesting that these differences were of little clinical relevance.

### Drawbacks

**Frequency and duration of bathing** Water is becoming an increasingly scarce and valuable resource, making it harder to justify the use of baths over showers without evidence of clinical benefit.

**Bath emollients** These products are extremely expensive compared with standard leave-on emollients.

**Washing of clothes** No patients had contact dermatitis to enzymes when patch-tested at the end of the study, and there was no evidence of specific blood IgE against any of the enzymes [273].

**Water softeners** These products represent a large capital expense for eczema patients.

### Comment

Although the study by Andersen *et al.* [272] was small, the virtual absence of any differences between the enzyme and nonenzyme detergents and the corresponding narrow confidence intervals provide convincing evidence of a lack of harmful effect. The study was not sponsored by industry.

The independently funded trial of ion-exchange water softeners also provides strong evidence for lack of effect of this intervention in the management of established eczema [276]. This was a large trial, with a low risk of bias and narrow confidence intervals around the objective primary outcome of eczema severity, making it unlikely that a clinically important effect had been missed.

### Implications for clinical practice

There is good evidence that water softeners do not provide additional benefit over normal care in the management of eczema. There is currently no evidence to suggest that parents should switch from a biological to a nonbiological washing powder. Further long-term studies using a pragmatic design are required to establish the role of bath emollients, frequency of bathing, and the most appropriate wash products to use.

### Key points: washing and bathing

- There is strong RCT evidence that softening hard water for washing and bathing does not improve the severity of established eczema.
- Although the parents of children with atopic eczema commonly avoid washing powders that contain enzymes (biological powders), evidence from a small RCT did not support the belief that washing detergents containing enzymes have a provoking effect on eczema severity in comparison with washing detergents without enzymes.
- There is limited evidence to suggest that fabric softeners may be less likely to exacerbate the symptoms of eczema; further pragmatic studies are needed.
- The role of soap substitutes and bath additives in the management of eczema requires further study.

### Can specialist clothing help reduce the symptoms of atopic eczema?

#### Efficacy

Wearing fabrics next to the skin has been suggested to be a physical irritant that can be a trigger for eczema. A small RCT showed that smooth fibers are less aggravating for eczema patients than rough fibers [277], and fabrics manufactured using warp-knit appear to be less irritating than jersey-knit fabrics, regardless of the fibers used [278]. Cotton, silk, and smooth manmade fibers have all been

used to create specialist clothing for people with eczema. These garments sometimes have added antimicrobial properties.

Three systematic reviews have evaluated the use of therapeutic clothing that has antimicrobial properties [279–281]; but no recent reviews were identified looking at all clothing or fabric-types.

The most recent systematic review [279] included a section on antimicrobial clothing and reported two RCTs of silk clothing [282,283] and two on silver-impregnated clothing [284,285]. Two further RCTs have examined the use of ethylene vinyl alcohol (EVOH) fiber [286,287], which does not have antimicrobial properties.

**Silk clothing** One trial included 22 children with mild to moderate eczema. It compared sericin-free silk tubular bandages (DermaSilk®) on one arm for 3 months against 2 weeks of sericin-free silk fabric without the antimicrobial properties of DermaSilk on the opposite arm, followed by cotton bandages for the remaining 10 weeks [282]. The second trial included 30 children and adults with atopic eczema. It compared sericin-free silk sleeves (Dermasilk) against the same fabric without the impregnated antimicrobial, used for 28 days [283].

Both trials hinted at the possible benefit of Dermasilk fabric using blinded outcome assessment of eczema severity, but they were too small and of too short a duration to inform clinical practice. No trials were identified for other brands of silk clothing.

**Silver-impregnated clothing** One trial included 68 adults with moderate eczema, and compared silver-coated undergarments (Padycare®) with cotton undergarments. Both were worn day and night for 2 weeks [284]. A second trial included 30 children and adults with “acute eczema.” Participants received one of three interventions for 2 weeks: silver-coated undergarments (x-static®); undergarments without the silver-coated fibers; or prednicarbate ointment 0.25% [285]. All participants could use prednicarbate ointment 0.025% as required throughout the trial.

Neither trial presented convincing evidence of efficacy. Interpretation of the trial findings is difficult owing to the small sample sizes, lack of blinding, and short-term duration of the trials.

**Ethylene vinyl alcohol fiber** EVOH is a smooth fiber that is reported to be highly hydrophilic with good biocompatibility. This product has been used for tissue engineering, vascular grafts, tissue repair, wound healing, and drug delivery.

An 8-week crossover RCT included 30 participants with well-maintained eczema and compared EVOH underwear (MEDIELE®) with cotton underwear. Each participant wore each type of underwear for 4 weeks without a wash-out period in-between the different fabrics [286]. A second RCT included 24 children aged 3–9 years with eczema and compared EVOH underwear with cotton underwear for a period of 4 weeks [287].

No significant differences in eczema outcomes were found between the groups in either of these small trials.

### Drawbacks

The main drawbacks for specialist clothing are its cost and limited availability.

None of the trials reported adverse events related to the use of specialist garments other than [285], in which one patient was reported to have 1 µg of silver per liter in their urine at day 28. No silver deposits were found on the skin or mucous membranes.

### Comment

The study of specialist clothing is challenging because of the inability to blind participants effectively, making it difficult to interpret the significance of patient-report outcomes. This is particularly problematic as the possible benefits of these garments may be at a sub-clinical level, impacting on overall comfort and improvements in sleep and quality of life. No studies have yet been conducted looking at the cost effectiveness of specialist clothing.

### Implications for clinical practice

There is no need for parents of children to buy expensive cotton clothes if their child finds that other fine-weave synthetics are just as comfortable.

On the basis of the limited trial data to date, it is not yet possible to establish whether specialist clothing provides measurable benefits for patients with eczema. Nevertheless, these garments are currently available on prescription and their popularity amongst patients is growing. A large, well-designed, pragmatic trial is needed to see whether such clothing offers a genuine benefit to patients with eczema.

### Key points: specialist clothing

- The roughness of clothing textiles may be more important for skin irritation than the type of textile fiber (synthetic or natural).
- Several types of specialist clothing are now available for the treatment of eczema, but the quality of the trials to date makes it difficult to assess their clinical benefit.
- Of the products currently tested in RCTs, silk garments are the only ones to have demonstrated significant improvements in eczema severity using blinded outcome assessments.
- A large, well-designed pragmatic trial is needed to see whether such clothing offers genuine benefits for patients with eczema.

### What is the role of psychological interventions for the treatment of atopic eczema?

#### Efficacy

Over the years, a range of psychological interventions have been used for the treatment of eczema, including behavioral management (often referred to as habit-reversal techniques), relaxation therapy, and cognitive behavioral therapy.

Two systematic reviews have looked at psychological interventions for eczema [288,289]. The first included psychological and educational interventions in children only, and the latter included all psychological intervention trials. The role of education in the management of eczema is discussed in the education section of this chapter. This section describes four RCTs of psychological interventions: two habit-reversal trials [290,291]; one relaxation with hypnotherapy and biofeedback trial [292]; and one trial including both relaxation and cognitive behavioral techniques [293]. A fifth trial included relaxation and habit reversal as part of an educational package, and this is described in the section on the role of education in the management of eczema [294], and one trial of brief dynamic psychotherapy was excluded as it was not randomized [295].

**Habit reversal** It has been postulated that scratching becomes a habit in atopic eczema, and that it is detrimental in patients with eczema because it further damages the skin. Habit reversal is a modified behavioral technique that teaches patients to recognize

the habit and then to progressively develop a “competing response practice,” such as simply touching, squeezing, or tapping the itching area, or to develop other ways of moving their hands away from the itching area [296].

In the first habit-reversal study [290] 17 patients with eczema aged 19–41 years were randomly assigned to two groups. The interventions consisted of hydrocortisone cream plus two sessions of habit-reversal treatment, received during week 1 (active-treatment group), or hydrocortisone cream alone (comparator group). The study was unblinded. At the end of the assessment period (28 days), the mean reduction in the global eczema score was 67% in the active-treatment group, in comparison with 37% in the comparator group ( $P < 0.05$ ). The total score for self-assessed annoyance was also markedly reduced in the active group in comparison with the other group. The mean percentage reduction of scratching episodes per day was 79% in the active-treatment group, in comparison with 49% in the comparator group ( $P < 0.01$ ).

In the later study conducted by the same team [291], 45 patients were randomly assigned to four groups for a period of 5 weeks. Group A applied hydrocortisone cream for the entire 5-week period; Group B applied betamethasone valerate (a potent topical steroid) for 3 weeks, followed by hydrocortisone for the remaining 2 weeks; group C applied hydrocortisone plus habit-reversal for the 5-week period; and group D had betamethasone plus habit-reversal for the first 3 weeks, followed by hydrocortisone plus habit-reversal for the remaining 2 weeks. The study was unblinded. Significant differences were reported between the behavioral-therapy groups and those taking steroids alone for “total skin status.” Scratching was reduced by 65% in the hydrocortisone-only group, 74% in the betamethasone followed by hydrocortisone group, 88% in the hydrocortisone plus habit-reversal group, and 90% in the betamethasone plus hydrocortisone plus habit-reversal group (statistics not presented).

**Relaxation with hypnotherapy and biofeedback** One 20-week trial included 44 children who had inadequately controlled eczema, despite conventional treatment [292]. Participants were allocated to three treatment groups: relaxation plus hypnotherapy; relaxation plus biofeedback; and a discussion group control in which children were encouraged to keep a treatment diary. All sessions lasted approximately 30 min, with four sessions in total at 2, 4, 6, and 8 weeks. The hypnotherapy sessions focused on reducing itching through guided imagery with a clinical psychologist, the biofeedback sessions used a “relaxometer” that gave feedback to participants about their level of relaxation using skin conductance, and the discussion control group discussed their symptoms on the basis of their diary responses.

Children in the hypnotherapy and biofeedback groups both showed a statistically significant reduction in the blinded outcome assessments of severity of surface damage and lichenification compared with the control group. For the combined relaxation groups there was a significant improvement after 20 weeks compared with baseline for surface damage ( $t = 2.2$ ;  $P = 0.04$ ) and lichenification ( $t = 2.39$ ;  $P = 0.027$ ). There was no improvement over time in the discussion (control) group. Drop outs were high for this trial, with 12/44 (27%) being excluded from the analysis at 20 weeks.

**Relaxation and cognitive behavioral therapy** One study evaluated the use of an autogenic training program (ATP) as a form of relaxation therapy versus cognitive-behavioral therapy (BT), versus a standard dermatological educational (DE) program versus com-

bined DE and BT (DEBT) [293]. A total of 113 secondary-care patients were randomly assigned to these four groups and were also compared with an additional standard medical treatment group, who were not part of the random assignment. The investigators were blinded to the group allocation. The intervention was for 3 months, and the patients were followed up for 1 year. At the end of 1 year, the mean skin severity lesion score dropped from 29.5 to 28.8 in the DE group, from 33.7 to 19.8 in the ATP group, from 31.0 to 20.7 in the BT group, and from 35.4 to 25.8 in the DEBT group. There were no significant differences in the mean severity of itching between the four groups. The DEBT treatment led to significantly greater improvement in global skin severity than intensive education (DE) alone, and this was also accompanied by significant reductions in topical steroid use. Overall, the drop-out rate was low (9/113; 8% at 3 months).

### Drawbacks

In the study by Ehlers *et al.* [293] the behavioral approaches required 12 weekly group sessions of 1.5–2 h, each with five to seven patients. No adverse events were reported in any of the trials, although some of the drop outs could possibly be related to the fact that extra visits were needed for the behavioral technique.

### Comments

The study by Ehlers *et al.* [293] and the study by Sokel *et al.* [292] carry more weight than the other two studies [290,291] as the assessments were made by an investigator blinded to the treatment allocation.

Despite methodological limitations, the magnitude of improvement for those receiving behavioral techniques in addition to standard dermatological care (which included topical corticosteroids) warrants further investigation.

### Implications for clinical practice

The combination of psychological therapy with judicious use of topical corticosteroids and emollients seems an attractive one, and evidence from four RCTs suggests that this approach may be successful. The exact components of the most effective psychological therapy package are still to be established, and the lack of suitably qualified personnel may limit the ability to deliver this intervention in many settings.

### Key points: psychological interventions

- Four RCTs suggested that psychological interventions such as habit-reversal, cognitive behavioral therapy, relaxation, hypnotherapy, and biofeedback are a useful adjunct to dermatological treatment in atopic eczema.
- Further studies are required to assess how these findings can be generalized to other settings and patient groups.

### What is the role of patient education in controlling the symptoms of atopic eczema?

#### Efficacy

This section deals with patient education as delivered to patients and their families. It does not explicitly deal with studies examining the impact of changes to service delivery. Three systematic reviews

were found [289,297,298] and one additional RCT [299] not included in any of the reviews. A total of 11 RCTs are described below [294,299–308]; two studies [309,310] were excluded, as there were participants with eczema and psoriasis (and did not present data in a disaggregated form).

Whilst the content of the training programs varied, information was generally covered relating to the nature of the disease, treatment options (including practical advice and treatment expectations), coping strategies/psychosocial support, and avoidance of allergens and irritants.

### *Efficacy*

**Adults with eczema** One 40-week study [294] of 54 adults aged 18–35 years in the Netherlands compared a 2-week (10 days) intensive day-school program made up of two 3-h sessions per day in groups of five participants with communal breaks against standard outpatient care. A significant improvement in quality of life between the treatments groups was reported, resulting in a median difference of 13 points after 40 weeks. The time taken for consultations showed a greater reduction after 40 weeks in the education program. A lower level of sick leave at 10 weeks in the education group which did not reach significance was not apparent at the end of trial.

One trial [299] randomized 80 adults with eczema to either a paper pamphlet or an online video containing the same eczema education information which could be used as often as desired for 12 weeks. There was a significantly greater satisfaction and level of knowledge with the online video compared with the pamphlet. The severity of eczema was also significantly reduced after 12 weeks in the online video group in comparison with the paper pamphlet group.

**Children with eczema, parents and carers** Three trials compared a single additional education session on top of usual care [302,303,307]. A trial [302] involving 61 children with eczema and their parents compared a 2-h group education session in addition to normal care. A significant decrease in eczema severity in the education group was reported at 4 weeks and 12 weeks. Quality of life improvement was only significant for children aged 5–16 years at 12 weeks, but not for children under 5 years. There was no significant on-family impact. A large primary care trial in the UK [303] compared a newly qualified dermatology nurse giving one 30-min consultation, compared with no consultation in 225 children with eczema. The control group was offered the same consultation after the end of the study. This “one-off” nurse education session did not appear to have any effect on the children’s quality of life after 12 weeks. The impact on the family improved after 4 weeks compared with having no consultation ( $P = 0.06$ ; mean difference,  $-0.79$ ; 95% CI,  $-1.62$  to  $+0.04$ ), but this effect was not present at 12 weeks. It is not clear whether there was any effect on the severity of eczema as no data other than baseline were provided. An open trial [307] evaluated the use of an “eczema school” for parents of 50 consecutive children seen in an outpatient setting (aged 4 months to 6 years). The families received either routine information from the treating physician, or a two hour visit with a trained dermatology nurse in addition to the physician visit. There was generally a trend towards improved outcomes for the group that had received the additional education sessions, but the results were poorly reported and are difficult to interpret. Improvements in disease severity were judged to be largely a result of better treatment compliance.

Three trials compared a program of additional education on top of usual care. A trial [304] of 151 children with eczema in the USA

used an individual, tailored session with a trained eczema educator for 15 min for the initial visit, with the level of follow-up being dependent on the severity of eczema. The control group was given standard care by a resident and attending pediatric dermatologist. It is not clear when the outcomes were measured, but no significant difference in severity was reported between the treatments. Two almost identical trials were reported by Staab and colleagues [300,301]. The first trial [301] compared a parental multidisciplinary education program, with 93 participants receiving one 2-h session a week for 6 weeks and 111 participants not receiving any sessions. A much larger study [300] by the same authors in Germany in 2006 looked at the use of a standardized group education program in 518 infants and children from 3 months to 7 years, 185 children aged 8–12 years with their parents, and 120 adolescents aged 13–18 years. The training programs for the two trials were almost identical and both trials followed the participants for 1 year. The parental education program in the first trial showed no significant reduction in severity after 12 weeks; however, the education programs for the three different age groups in the second trial reported significant reductions in eczema severity in the education group in comparison with the control group. The adolescents (13–18 years) had the most significant improvement, with a reduction of  $-14.5$  points ( $P < 0.0001$ ). The older children (8–12 years) had a reduction in severity of  $-8.2$  (95% CI,  $-13.6$  to  $-2.8$ ;  $P = 0.003$ ). The infants and young children (3 months to 7 years) had a reduction in severity of  $-5.2$  (95% CI,  $-8.2$  to  $-2.2$ ;  $P = 0.0002$ ). Both studies by Staab and colleagues found significant reductions in quality-of-life scores. In the smaller 2002 trial [301], the “confidence in medical treatment” subscale was the only one to show a notable benefit from one session of education. In the much larger trial in 2006 [300], the 3 months to 7 years age group showed a significant benefit of education for all five subscales. The 8–12 years age group showed a benefit of education for the confidence in medical treatment, emotional coping, and acceptance of disease subscales. For all the significant differences in quality of life, the absolute difference in points reduction was small: between 1 and 3 for all scales. An assessment of how itching behavior was affected by education in 8–18-year-olds found that catastrophication (thoughts of not being able to cope) significantly improved, but that coping did not improve. Education was found to be the biggest predictor of change in treatment behavior using logistic regression.

One small study from Brazil [306] in 36 families with a child of 2–16 years with moderate to severe eczema compared attending fortnightly 90-min support group sessions for 6 months with a control group. It was not clear whether the control group had any intervention or not during the study. For the support group intervention, the children and adults were taken into separate sessions and joined together for a short time at the end. The frequency of pruritus decreased in the support group compared with baseline, but it is unclear whether this was significantly better than the control group. The influence of itching on the participant’s mood was statistically significantly reduced in the support group compared with the control group after the intervention, but this was a relatively small absolute difference. The children’s quality of life (CDLQI) was reported as statistically significantly different as a whole, after the intervention ( $P = 0.01$ ). The leisure ( $P = 0.04$ ) and personal relationships ( $P = 0.02$ ) were reported as statistically significantly improved in their own right for the support group compared with the control group. No data were given for these reported statistical differences.

A small trial in Germany [308] randomly assigned 30 children aged 3–6 years with moderate to severe atopic eczema to either a 10 min demonstration with a Kardoff–Schnelle–Parker skin model or a control group verbal instructions of the same duration as a standard consultation. The skin model is made of chamois leather and allows the children to experience for themselves the difference between well-moisturized and neglected skin. The sessions took place at baseline and again at 14 days. The main outcome of eczema severity was assessed blindly at 0, 14, and 42 days. Children allocated to the active group showed significant improvements in their SCORAD scores at 42 days ( $P < 0.006$ ).

Another trial [305] allocated patients to one of three groups: parental education ( $n = 18$ ); standardized video education for parents plus a handbook ( $n = 15$ ); or standard eczema therapy and follow-up ( $n = 14$ ). There were significant differences between the groups at baseline in terms of disease severity and maternal education that were not adjusted for in the analyses. Significant improvements were seen for the education groups in comparison with the control group in relation to disease severity, sleep, itch, and quality of life, although multiple hypothesis testing meant that the implications of these findings were difficult to assess.

### Drawbacks

There was no information reported on adverse events or other disadvantages from any of the trials of educational interventions.

### Comments

Around half of the trials clearly described an appropriate method of randomization and allocation concealment. Blinding of the outcome assessors, which in most trials was both the investigators and the participants, was either not clearly described, not attempted, or not possible owing to the differences in treatment between the groups. Several of the trials had high numbers of participants who did not complete the trial and were not included in the analyses.

### Implications for practice

For adults, an intensive education course shows some evidence of benefit, but this would probably have meant 2 weeks off work, which on its own could lead to an improvement in a chronic condition such as eczema. The format of the education should be taken into account for adults as it appears to have a significant impact. Offering choice of format may be a good way to maximize the benefit for individuals.

The education programs for parents, young children, and adolescents appear, on average, to confer some benefit, mostly by reducing severity or increasing disease-related quality of life, or both. The effects appear to be complex and may be related to age, presence or absence of parents or children, and format of the education and the providers of the education. There is not yet enough evidence to recommend a particular format or content for educational interventions. It is worth noting that adolescents (13–17 years) that were educated mostly without their parents showed the greatest decrease in eczema severity, although the large numbers of drop outs were not included in the analyses for this trial. This age group is also more likely than younger children to improve spontaneously, so this must be treated with some caution. The most interesting result from the only trial to have looked at the role of support groups is that the quality of life and effect of itching on mood of the children with eczema significantly improved whilst impact on the whole family did not. This trial [306], along with evidence from other trials, hints at the potential benefit of child-

focused, semi-structured support groups for children with eczema, although which particular aspect or aspects of the group support may be conferring this benefit needs much more detailed investigation.

The wider applicability of the educational interventions trialed is difficult to interpret, as an educational intervention developed in one country or in a particular population may not have the same effect in another. None of these trials has yet reported potential harms of educational interventions or the cost effectiveness of these interventions and their suitability for use in routine practice, points which must be considered when managing patients and their families using education.

### Key points: patient education

- Seven randomized controlled trials have been reported that broadly support the role of education in the treatment of atopic eczema (although some lacked power to show an effect).
- Most trials included children or adults with moderate or severe disease.
- The evidence to support the use of multidisciplinary education packages in group therapy sessions is better than that for individualized therapy.
- There is evidence to support “child-focused” education, particularly for older children and adolescents with eczema.
- Trials of individual therapy based on a single consultation with a health professional were less conclusive and require further investigation.
- Positive results have been observed up to 1 year following delivery of the education intervention.

### Case scenario 24.2: How should infected atopic eczema be treated?

Bacterial, viral, and fungal infections may be associated with atopic eczema (Figure 24.2). Infections need to be promptly recognized and treated. Confusion arises because atopic eczema skin may be colonized with pathogens in the absence of signs of clinical infection. The role of these pathogens in aggravating eczema is unclear, and the distinction between what constitutes clinically infected and noninfected eczema requires further clarification.

The relationship between *S. aureus* and atopic eczema disease activity has been debated for many years. Most physicians recognize clinically infected eczema as recent onset of weeping, oozing, and serous crusting or overt pus overlying the eczematous lesions. In this situation, *S. aureus* is isolated in 90–100% of cases, usually in high numbers [311,312]. Recent reports show increasing emergence of methicillin-resistant *S. aureus* in eczema sufferers [313–316]. In around 30% of cases,  $\beta$ -hemolytic streptococci are also isolated [311]. Recurrent clinical infections are a major problem for some atopic eczema sufferers [317].

*S. aureus* is also isolated from the lesions of atopic eczema in 50–90% of patients without overt signs of infection [318,319]. Some studies have shown that *S. aureus* may promote inflammation through superantigen activation [320].

The significance of the yeast *Malassezia furfur* in atopic eczema is also a subject of debate. It exists in two forms: *Pityrosporum ovale* and *Pityrosporum orbiculare*. There is some evidence that it can act as an allergen, stimulating both positive radioallergosorbent tests (RASTs), and positive patch tests, which may exacerbate eczema [321,322]. It has been particularly implicated in atopic eczema of the head and neck [323].

Figure 24.2 Infected atopic eczema.

The idea that bacteria and fungi may act as immunogenic stimuli contributing to atopic eczema activity has led to a large increase in the use of anti-infective agents in nonclinically infected atopic eczema over the last 20 years. This section evaluates the possible benefit of these agents.

A Cochrane systematic review “Interventions to reduce *Staphylococcus aureus* in the management of atopic eczema” [281] and its subsequent update [324] are the source of much of the data in this section. We searched the GREAT database for further RCTs up to end 2011 (<http://www.greatdatabase.org.uk/>).

A total of 10 RCTs evaluating the possible benefit of oral or topical antimicrobials in clinically infected atopic eczema were included and are summarized in Web Table 24.7. An additional eight RCTs evaluating the possible benefit of antiseptics in noninfected atopic eczema are presented in Web Table 24.8. Further RCTs of topical steroid–antibiotic combinations in noninfected eczema are shown in Web Table 24.9.

### How useful are systemic antibiotics?

#### Efficacy

**Clinically infected eczema** Two RCTs evaluating systemic antibiotics for clinically infected eczema were located (Web Table 24.6) [312,325].

A study of oral cefadroxil showed significant benefit over placebo for all clinical and microbiological outcomes [312].

Erythromycin acetate and erythromycin stearate both improved clinical and microbiological outcomes. There was no significant difference between the preparations [325].

**Clinically uninfected or unspecified eczema** Two further important RCTs have compared systemic antibiotics with placebo in the treatment of noninfected atopic eczema. In the first [326], oral flucloxa-

cillin 250 mg four times daily for 4 weeks showed no benefit over placebo in terms of clinical efficacy, despite significantly reducing *S. aureus* counts. The second study [327] showed a similar absence of benefit for 2 weeks’ oral cefuroxime. Rapid recolonization occurred in both groups after cessation of treatment.

#### Possible drawbacks

Gastrointestinal side effects occurred in 50% of patients in each group taking erythromycin, one patient on cefuroxime, and 6.5% of patients on cephalexin. Emergence of methicillin-resistant *S. aureus*, which persisted for 2 weeks after completion of treatment, was noted in the flucloxacillin study.

#### Comments

The existing studies are old, and quality of reporting was generally poor, with small numbers of patients and a lack of detail regarding concurrent treatments and clinical outcomes.

#### Clinical implications

It is common practice to prescribe a short course of oral antibiotics in acute infected eczema. There is some evidence that this improves clinical signs of infection, and there is no evidence of a detrimental effect. In contrast, there is no evidence to support the use of longer term antibiotics in people with atopic eczema whose skin is colonized with *S. aureus*, and there is some evidence that use of such antibiotics may promote antibiotic resistance.

### Do topical antibiotics have a role in infected eczema?

#### Efficacy

**Clinically infected eczema** One RCT has evaluated topical antibiotics in the treatment of clinically infected eczema (Web Table 24.6).

Gentamicin was significantly less effective at reducing dermatitis activity than betamethasone valerate–gentamicin or betamethasone valerate alone [328].

**Clinically uninfected or unspecified eczema** Two RCTs have looked at topical antibiotics in noninfected eczema. One crossover study comparing 2% mupirocin ointment versus placebo in adults and children found a significant reduction in *S. aureus* in the mupirocin group compared with the placebo in the first period. However, recolonization occurred during the 4-week follow-up period [329]. A further study showed that fusidic acid 2% cream resulted in more treatment failures than hydrocortisone–fusidic acid [330].

#### Possible drawbacks

Minor skin irritation or eczema flare occurred in 18% of patients in the fusidic acid group, in comparison with only 3% in the steroid–fusidic acid group [330].

#### Comments

Topical antibiotics appear to be effective at reducing *S. aureus*, but clinical benefit of antibiotic alone is limited. Rapid recolonization occurs after cessation of treatment. Studies did not look for emergence of resistant organisms.

#### Clinical implications

The role of short-term topical antibiotics in infected atopic eczema is unclear. They may be a useful addition to topical steroids, but there is a lack of information regarding comparison between oral and topical antibiotics in this situation. Long-term use in

noninfected eczema should be avoided owing to risk of antibiotic resistance.

### Are topical steroid–antibiotic combinations more effective than topical steroids alone in clinically infected atopic eczema?

#### Efficacy

**Clinically infected eczema** We found six studies evaluating topical steroid–antibiotic combinations for clinically infected eczema (Web Table 24.6). Several other studies have not been included because they include less than five patients, or results for atopic eczema could not be separated from other dermatoses.

Two studies compared topical steroid–antibiotic combinations versus placebo. The study by Thaci *et al.* [331] showed superior benefit of betamethasone–fusidic acid ointment and cream over vehicle alone. A similar study showed superior benefit of both betamethasone/fusidic acid lipid cream and betamethasone–fusidic acid standard cream formulation compared with lipid cream vehicle alone [332].

Three RCTs have compared topical steroid–antibiotic combinations versus topical steroid alone. There was no significant difference in clinical signs or symptoms between betamethasone valerate–fusidic acid [333] versus betamethasone valerate, or between betamethasone valerate–gentamicin versus betamethasone valerate [328].

Most recently, Gong *et al.* compared mupirocin plus hydrocortisone butyrate versus vehicle plus hydrocortisone butyrate in a mixed group including 119 patients with atopic dermatitis, infected and noninfected. There was no difference in the global severity scores (EASI) or isolation rates of *S. aureus* between the groups at days 7, 14, or 28 [334].

One RCT has compared different steroid–antibiotic combinations. There was no significant difference between 0.1% betamethasone–2% fusidic acid and 0.1% betamethasone–0.5% neomycin in terms of clinical efficacy or ability to eradicate *S. aureus* [335].

**Clinically uninfected or unspecified eczema** Six further RCTs were located that have evaluated topical steroid–antibiotic combinations in nonclinically infected atopic eczema (Web Table 24.8).

Five of the RCTs compared topical steroid–antibiotic combinations versus topical steroid alone. One study of 30 participants with severe atopic eczema found clobetasol propionate 0.05% cream was as effective as betamethasone valerate 0.1% cream plus neomycin at reducing *S. aureus*, and significantly better at improving global outcome [336].

One study of 36 participants found that fluocinolone acetonide plus 0.5% neomycin sulfate cream significantly reduced the amount of *S. aureus* isolated compared with fluocinolone acetonide cream alone [318].

A further study found that 2% fusidic acid plus 1% hydrocortisone was significantly better than 1% hydrocortisone alone at reducing *S. aureus*, but there was no benefit in reducing atopic eczema activity [330].

Schuttelaar and Coenraads compared 3% tetracycline plus 0.1% triamcinolone versus 0.1% triamcinolone in 44 adults with moderate/severe atopic eczema and found no significant difference in SCORAD at the end of treatment. Significantly fewer people on the combined group had *S. aureus* isolated at the end of the study [337].

The most recent study of 60 children and adults with moderate to severe eczema found no significant difference in clinical scores (SCORAD) at 8 weeks between fluticasone propionate 0.05% cream versus tacrolimus 0.03% ointment, versus fluticasone plus 2% fusidic acid versus tacrolimus plus 2% fusidic acid. All groups reported a decrease in colonization rate of *S. aureus* after 2 and 8 weeks of treatment. Tacrolimus alone was slower to reduce *S. aureus* than fluticasone alone (significant difference at 2 weeks) with no significant benefit from the addition of fusidic acid [316].

Pooled analysis in the Cochrane review of two studies [318,337] showed an 83% reduction in the isolation rate of *S. aureus* in the combination groups compared with steroid alone at the end of treatment.

One RCT compared different steroid–antibiotic combinations. There was no difference in clinical improvement or *S. aureus* reduction between 2% fusidic acid–0.1% betamethasone cream versus 2% mupirocin ointment plus 0.1% betamethasone cream [338].

#### Possible drawbacks

Minor skin irritation, flare of dermatitis, and possible hypersensitivity reactions occurred in 1–3% of patients across the groups. Pooled results from two studies [330,337] in the Cochrane review found no significant difference in adverse events requiring withdrawal from treatment; however, there were significantly fewer minor adverse events not requiring withdrawal from treatment in the combination groups [281]. One study reported emergence of fusidic-resistant strains of *S. aureus* in two patients after 8 weeks of fusidic acid treatment [316].

#### Comments

There is evidence that topical steroid–antibiotic combinations are effective in the treatment of clinically infected atopic eczema, but there is a lack of evidence to determine how they compare with oral antibiotics combined with topical steroids or with topical steroids alone.

There is no evidence to suggest benefit for the use of topical steroid–antibiotic combinations over topical steroids alone in noninfected eczema. Topical steroid–antibiotic combinations appear to be more effective at reducing *S. aureus* than topical steroids alone, but this does not translate to clinical benefit. Rapid recolonization occurs on cessation of treatment, and hypersensitivity and bacterial resistance may develop.

#### Clinical implications

There is no good evidence for the use of topical steroid–antibiotic combinations. If they are used, they should be limited to short-term (<2 weeks) use for clinically infected eczema as per National Institute for Health and Clinical Excellence guidelines, UK [52]. There is no evidence to support long-term use in noninfected eczema and there is potential for harm.

### How effective are antifungals?

#### Efficacy

**Clinically infected eczema** There are no RCTs of antifungal treatments in infected eczema.

**Clinically uninfected or unspecified eczema** We identified six RCTs evaluating antifungal treatment for noninfected atopic eczema.

Three RCTs compared oral antifungals with placebo. In the first study, 80 patients with atopic eczema and positive skin prick or

RASTs to yeasts were randomized to ketoconazole 200 mg daily for 30 days or placebo. The ketoconazole group showed significant improvement compared with baseline at 30 days, not seen in the placebo group. Benefit was most marked in the group with positive skin cultures for *P. ovale* [339].

One study showed no difference in clinical benefit between 3 months' ketoconazole and placebo despite reduction in specific IgE to *M. furfur* and other yeasts [340].

One study compared itraconazole 200 mg daily or 400 mg for 7 days with placebo. There was significant reduction in SCORAD at day 7 in the itraconazole groups compared with placebo, but no significant difference in patient or investigator global outcome in any of the groups [341].

A further three RCTs were located which looked at the role of topical antifungals. One study [342] attempted to evaluate antifungals in atopic eczema of the head and neck area. Miconazole-hydrocortisone cream plus ketoconazole shampoo was compared with hydrocortisone cream plus placebo shampoo. There was a significant benefit in favor of miconazole-ketoconazole for reduction in *P. ovale*, but there were no significant differences between the groups with regard to clinical outcome. One study [343] compared 1% ciprofloxolamine cream twice daily for 28 days with base cream for head and neck eczema. No other treatments were allowed. The investigator's global assessment showed significantly better improvement in the ciprofloxolamine group over the study period, but the difference in EASI scores was not significant. The third study showed no benefit of hydrocortisone 1%-miconazole cream over hydrocortisone 1% alone in 30 children with atopic eczema of elbows and knee flexures [344].

### Possible drawbacks

No adverse effects were documented in most of the studies. Two patients on long-term (3 months) ketoconazole reported nausea and abdominal pain. With topical antifungals, minor skin irritation and possible hypersensitivity reactions were seen in up to 5% of patients across the groups.

### Comments

It is difficult to draw conclusions about the role of antifungals from these small and disparate studies. More work is needed to determine the relevance of positive cultures, skin prick tests, and patch tests to yeasts in patients with eczema of the head and neck.

### Clinical implications

There is no current evidence to support the routine use of antifungals in the treatment of atopic eczema.

### How useful are antiseptic agents in clinically infected atopic eczema?

This section includes topical antiseptics, antiseptic emollients, bath additives, and other antiseptic treatments. Impregnated fabrics and clothing with antimicrobial properties have been discussed in the section on specialist clothing.

Ten RCTs were located which evaluated the use of antiseptic agents in atopic eczema (Web Tables 24.6 and 24.7).

### Efficacy

**Clinically infected eczema** Two RCTs considered antiseptics in clinically infected eczema. Thirty-one children with moderate/severe eczema pretreated with 2 weeks of oral cephalixin were

randomized to bath water with added bleach plus nasal mupirocin versus normal bath water and nasal vehicle ointment. The study reported a greater mean reduction in EASI in the bleach-mupirocin group at 1 month and at 3 months compared with placebo on the body and extremities, but not on the head and neck (which the bleach did not treat) [315].

Another study of prednicarbate 0.25% cream plus dodecyl dimethyl-ammonium chloride 0.25% versus prednicarbate 0.25% cream in adults found no significant difference in global outcome at the end of treatment. Isolation of *S. aureus* was similar between groups [345].

**Clinically uninfected or unspecified eczema** Eight RCTs considered antiseptics in nonclinically infected eczema (Web Table 24.7).

**Topical antiseptics** One study of 15 children and adults with mild to moderate eczema reported a statistically significant improvement in *S. aureus* colony counts and appearance of skin lesions with povidine-iodine vs. no treatment. However, no numbers were provided and group analysis was not performed [85].

One study in 21 adults compared hyperforin 1.5% (St John's wort) cream versus placebo in a half side comparison study, and showed significantly greater reduction in SCORAD on the treatment side. No data were given on the number of patients in each group [346]. A further study (no numbers given) compared 0.2% farnesol plus 5% xylitol cream versus placebo and reported a significant improvement in dryness and scaling in both groups. At the end of treatment there was no difference between the groups in change of *S. aureus* from baseline [347].

The most recent study by Tan *et al.* compared triclosan 1% leave-on emollient cream versus vehicle cream in 60 patients all using concurrent 0.25% betamethasone valerate. At day 14 there was a significant greater decrease in SCORAD from baseline in the triclosan group compared with placebo, but by day 27 the difference was not significant. The mean total amount of steroid cream used was significantly less in the triclosan group (22 g vs 44.2 g), suggesting some possible steroid-sparing effect [71].

**Antiseptic bath additives and wash products** Two RCTs have compared a standard bath emollient, Oilatum (acetylated wool alcohols 5%, liquid paraffin 63.4%), with an emollient plus antiseptic, Oilatum Plus (benzalkonium chloride 6%, triclosan 2%, light liquid paraffin 52.5%). No significant differences were demonstrated in terms of clinical or microbiological outcomes [348,349].

A further study compared a soap containing 1.5% triclocarban with an identical placebo soap. The authors state that the global change in atopic eczema severity was significantly greater in the treatment than in the placebo group, but the actual data are missing. Graphic data suggest a similar degree of improvement in both groups [350].

One RCT compared a proprietary brand of chlorhexidine with a 1:20 000 dilution of potassium permanganate, in addition to topical steroid in both groups, and found no significant differences in the clinical or bacteriological outcomes [351].

### Drawbacks

Skin irritation, pruritus, and worsening of dermatitis were the main side effects reported in the studies in which adverse events were documented. These were reported more frequently overall in the antiseptic-treated groups.

### Comments

There is no clear evidence of additional benefit for the use of antiseptic agents in atopic eczema. The use of bleach baths appears to have some benefit, but the numbers of patients colonized with *S. aureus* was unchanged from start to the end of the study; therefore, it is not possible to attribute this benefit to reduced bacterial colonization.

### Clinical implications

Antiseptic-containing preparations are in common use in the management of atopic eczema. There is no evidence to support their routine use. It is accepted clinical practice to use antiseptics in patients with recurrent clinical infection. More studies are needed to determine whether this is beneficial, and which antiseptic agents are most effective.

#### Key points: anti-infective agents

- Twenty four RCTs of anti-infective agents are reported, the majority in nonclinically infected eczema.
- Clinically infected eczema needs to be promptly identified and treated, but there is a lack of evidence regarding best treatment.
- One small study shows a possible benefit of bleach baths and nasal mupirocin after oral antibiotic treatment of infected eczema.
- Anti-staphylococcal agents are effective at reducing *S. aureus* to a greater extent than controls, but there is a lack of evidence of clinical benefit over nonantimicrobial agents in noninfected eczema.
- The few, small studies of antifungal agents in atopic eczema do not show clear evidence of benefit.
- Adverse events reported with antimicrobial agents are low, but there remains a risk of emergence of resistant organisms after prolonged treatment.

### Case scenario 24.3: an adult with severe atopic eczema

Figure 24.3 shows a case of severe atopic eczema.

#### What is the role of systemic immunosuppressive therapy?

The systematic review by Hoare *et al.* published in 2000 described several older and experimental immunomodulatory therapies for atopic eczema, including platelet activating factor, immunoglobulins, interferon gamma, and levamisole [49]. Some showed promising results in small studies, but they were not developed further or tested in larger trials. This section concentrates on systemic immunosuppressive agents that are commonly used in dermatology, such as ciclosporin, systemic steroids, azathioprine, and methotrexate, as well as phototherapy and photochemotherapy. A systematic review of systemic treatments for atopic eczema based on 27 studies including 979 participants was published in 2007 [352]. A further four systematic reviews covering trials of ciclosporin, azathioprine, efalizumab, and desensitization therapy have also provided additional data for this section [352–355].

#### Efficacy

**Systemic steroids** Systemic prednisolone is commonly used in short bursts (a few weeks) in order to get severe atopic eczema into remission. Three older RCTs have suggested that the short-term effect of oral steroids is large in comparison with placebo (Web Table 24.8) [356–358]. Relapse rates were not reported in these studies.

Oral steroids have not been evaluated for more than 4 weeks in atopic eczema. An RCT comparing prednisolone at a dose of 0.5–0.8 mg/kg for 2 weeks followed by placebo for 4 weeks against ciclosporin (2.7–4.0 mg/kg) for 6 weeks had to be stopped prematurely because of a very high drop-out rate due to disease exacerbations, mainly in the prednisolone group. Overall, one out of 21 patients in the prednisolone group achieved stable remission compared with six out of 17 in the ciclosporin group ( $P = 0.031$ ), prompting the authors to conclude that prednisolone is not suitable for inducing a stable remission in severe eczema [359].

**Ciclosporin** The systematic review by Schmitt *et al.* identified 11 studies evaluating the efficacy of ciclosporin in atopic eczema [352], although the other systematic review published around the same time by the same team identified another four studies [253]. Of the 15 studies in the review, which included 602 participants, eight were RCTs (two dose-finding, three double-blind parallel studies, and three crossover studies). Only one trial used an active control – a trial of 30 participants that compared oral ciclosporin against topical tacrolimus, which was inconclusive and confounded by topical corticosteroid use [360]. The general quality of the reporting was poor, except in two studies. The review showed some evidence of publication bias (i.e., larger treatment effects in smaller studies) and the authors suggested caution in interpreting the summary results [253]. The systematic review considered that 12 of the studies were sufficiently similar to allow quantitative pooling of data, and found a clear dose–response effect. At 2 weeks, the overall mean decrease in disease severity was 22% (95% CI, 8–36%) at a dose of 3 mg/kg and 40% (95% CI, 29–51%) for doses of 4 mg/kg and above. After 6–8 weeks of therapy, the mean pooled decrease in severity was 55% (95% CI, 48–62%). Effectiveness appeared to be similar in children and adults, although tolerability might be better in children. There is little doubt that ciclosporin is effective in severe atopic eczema, but it is only useful for short-term treatment because of kidney toxicity.

Figure 24.3 Severe atopic eczema.

**Azathioprine** One crossover RCT of azathioprine (2.5 mg/kg) versus placebo in 37 adults with severe atopic eczema was reported by Berth-Jones *et al.* in 2002 [361]. After 3 months' treatment, those receiving azathioprine had a 26% reduction in disease severity, in comparison with 3% of those on placebo, in an ITT analysis. A subsequent systematic review of unlicensed use of azathioprine for people with severe atopic eczema included 10 studies of 319 patients [353]. Only two of the included studies were RCTs, and both showed decreases in eczema severity compared with placebo. A subsequent RCT of 42 patients with severe atopic eczema comparing azathioprine against oral methotrexate concluded that both drugs reduced severity by a useful amount (42% vs 39% for methotrexate vs azathioprine, respectively) [362], although the trial was too small to demonstrate therapeutic equivalence [363].

**Oral pimecrolimus** One RCT examined the use of three different doses of oral pimecrolimus versus placebo in 103 patients with moderate to severe atopic eczema and found good treatment responses (67% at 7 weeks for the 30 mg twice-daily group) and no signs of nephrotoxicity or hypertension [364].

**Methotrexate, mycophenolate, infliximab, and other biologics** One prospective, open-label study suggested that oral methotrexate is well tolerated and is associated with a sustained reduction in disease activity (55% at 24 weeks) in severe atopic eczema, and suggested that an RCT is now warranted [365]. A subsequent trial of methotrexate versus azathioprine has already been discussed above. The systematic review of systemic therapies describes two uncontrolled studies of mycophenolate mofetil in 20 patients with severe eczema, with a mean decrease in disease activity of 55% and 68% at 8 weeks and 12 weeks, respectively [352]. The authors also reported another small uncontrolled study of infliximab (5 mg/kg) infusions in nine patients, and found that only two patients experienced greater than 50% improvement at 10 weeks [352]. Such uncontrolled studies are difficult to interpret, owing to assessment bias and regression to the mean, especially when patients with severe disease are recruited. A systematic review of efalizumab (a monoclonal antibody that targets T cell activation) found little evidence to support its use [354], and the drug has since been withdrawn owing to the rare but serious adverse effect of progressive multifocal leukoencephalopathy. The use of other biologics in severe atopic eczema is largely speculative [366,367]. One pilot RCT of omalizumab (a monoclonal antibody to IgE) for severe atopic eczema suggested that successful reduction in IgE was not accompanied by clinical benefit [368]. Like the field of psoriasis, several biologics are likely to be developed and tested for severe atopic eczema, and readers should consult the GREAT database for the latest evidence in this rapidly moving field (<http://www.greatdatabase.org.uk/>). Other approaches, such as desensitization immunotherapy, do not appear promising at present [355].

**Phototherapy and photochemotherapy** A total of 11 RCTs were identified, and these are summarized in detail in Web Table 24.9. All but four [369–372] were described in the systematic review by Hoare *et al.* [49]. The quality of reporting in most of the studies was poor. Most studies were underpowered to exclude clinically important differences between different forms of ultraviolet light, with overlapping confidence intervals between the effect estimates of the different groups. It is also unclear to what extent systemic effects may obscure comparisons of two different types of ultraviolet light

used in the same individual – that is, designs that irradiate one half of the body with one type of light and the other half with another type of irradiating light [373]. Broadly speaking, light therapy appears to be very effective in comparison with placebo (using ordinary fluorescent light) for atopic eczema, although it should be noted that tanning compromises blinding in such placebo studies. A subsequent systematic review by Meduri *et al.* summarized just nine trials of ultraviolet light therapy for atopic eczema and concluded that, for acute eczema, ultraviolet A1 (UVA1) appears to be fast and effective and that, for chronic eczema ultraviolet B (UVB) may be more effective, especially for narrowband UVB [374].

A further interesting Norwegian study indirectly assessed the role of ultraviolet light by randomly assigning 30 children to a holiday in the semitropical Canary Islands and 27 at home in cooler Norway [375]. Not surprisingly, the children randomly assigned to the Canary Islands improved more in terms of reduction in eczema scores and quality of life during the holiday, and such an effect was sustained for 3 months after the intervention. It is difficult to separate the effect of ultraviolet light from temperature or sea-water effects, as well as other differences such as diet and psychological effects, between the holiday locations. Nevertheless, the study suggests that a sunny holiday may have a sustained benefit on children with chronic eczema.

### Drawbacks

All of the immunosuppressants currently available carry potentially serious side effects, such as kidney damage (cyclosporin), bone-marrow suppression (azathioprine and methotrexate), osteoporosis (systemic steroids), liver fibrosis (methotrexate), and skin cancer (phototherapy) [49,352]. Long-term effects of oral prednisolone are well known and include hypertension, weight gain, osteoporosis, fat redistribution, diabetes, and acne, although the frequency of such complications when the treatments are used for a few weeks or months to gain control in severe atopic eczema is unknown [49]. The systematic review of cyclosporin found that adverse effects such as gastrointestinal upset occurred in around 40% of patient-months described in 15 studies [253]. An increase in baseline serum creatinine over 30% was found in 115 of patients, hypertension in 6%, and infections in 12% of patients [376]. Kidney damage can occur within a year of cyclosporin treatment and be permanent [377]. Treatment appeared to be better tolerated in children, although this may be partly due to larger doses being used in adults. For azathioprine, bone-marrow toxicity may be minimized by assessing blood thiomethylpurine transferase activity beforehand, although the test may not be widely available. In the RCT of azathioprine, 16 of the 37 participants withdrew (12 when on azathioprine and two on placebo), 14 developed gastrointestinal disturbance, two developed leukopenia, and eight had abnormal liver function tests [361].

Although the one RCT of oral pimecrolimus found minimal side effects (one patient in the placebo group had chest and abdominal pain, an abnormal electrocardiogram, and sinus bradycardia; and one patient in the pimecrolimus group had elevated fasting plasma glucose levels) [364], concerns associated with carcinogenicity in animals have prevented this form of therapy from becoming more widely available [185]. More data are needed on methotrexate, azathioprine, mycophenolate, and biologics in atopic eczema, as the numbers treated so far with these agents are far too small for it to be claimed that they are safe in either the short term or long term.

The short-term drawbacks of ultraviolet therapy include burning and itching, and they can usually be overcome by light testing before therapy and the use of emollients after treatment. Some

people find ultraviolet cabinets claustrophobic, and some very young children find the experience frightening. The long-term effects of giving ultraviolet light to young children with atopic eczema in terms of melanoma and non-melanoma skin cancer are unknown [49], and caution should be taken when extrapolating guidance based on adults receiving photochemotherapy for psoriasis, especially since susceptibility to melanoma may be enhanced in childhood.

### **Clinical implications**

Both ultraviolet light and systemic treatments such as short courses of ciclosporin are probably useful and safe in the person depicted in the case scenario. The choice of treatment would be largely determined by the person's preferences and local availability of treatment. Safety is a factor limiting the long-term use of all of these agents. Planned short-term use (2–3 months) to try to obtain a remission or give the person a “holiday” from severe symptoms seems a reasonable option, resorting to topical treatments such as intermittent use of potent topical steroids or tacrolimus once control is achieved. It is unclear at this stage whether different genetic subtypes of atopic eczema (e.g., those with a major barrier defect as determined by mutations in the filaggrin gene [378]) respond differently to different systemic treatments. Future trials should consider biomarker-based stratification using genetic or other biologic markers for disease-modifying strategies [40], or strategies that interfere with development of autoimmunity which may contribute to the chronicity of severe atopic eczema [379].

#### **Key points: systemic immunosuppressive therapy**

- There is reasonable RCT evidence to support the use of oral ciclosporin for severe atopic eczema.
- Kidney damage limits the long-term use of ciclosporin to a few months, with a return to conventional topical treatment once control is maintained.
- There is some evidence that both azathioprine and methotrexate are effective for the control of severe chronic atopic eczema, but the evidence base is still relatively small and short term, and both drugs require careful monitoring.
- One trial has shown that oral pimecrolimus was beneficial in moderate to severe atopic eczema, but oral pimecrolimus is not licensed because of concerns about the possible long-term development of lymphomas.
- RCTs on other potentially useful treatments, such as mycophenolate or biological therapies in patients with atopic eczema, are still lacking.
- Phototherapy (e.g., UVA1 for acute eczema and narrowband UVB for chronic eczema) has consistently been shown to be beneficial in atopic dermatitis, but both are limited by the long-term risk of skin cancer after many treatments.
- There is an urgent need for studies that compare systemic therapies against each other rather than against placebo for people with severe atopic eczema.
- There is a need for longer term studies of systemic immunosuppressive treatment for atopic eczema, in order to evaluate long-term safety and whether the use of these agents alters the natural history of the disease.

### **General summary observations on the evidence base for atopic eczema**

- Although around 600 RCTs have been conducted for atopic eczema, their ability to inform us about the everyday management of patients is still limited.
- Many people with atopic eczema are treated in the community, yet community-based trials are very rare in this field.
- Most of the trials of people with atopic eczema have reflected the agenda of the drug industry.
- New drugs have often been only compared against placebo in trials, rather than being compared against existing active treatments, which makes it difficult for clinicians and patients to decide which is best. Independent comparative effectiveness research is needed in order to make head-to-head comparisons.
- Some of the limitations of the atopic eczema evidence base are due to a generally poor quality of study reporting. All dermatology journals have a role to play by insisting on the basic standard of clinical trial reporting, as outlined in the Consolidated Standards of Reporting Trials 2010 statement (<http://www.consort-statement.org>).
- All future clinical trials in atopic eczema should be registered prospectively before recruitment starts in order to minimize selective reporting outcome bias and publication bias.
- Outcome measures used in atopic eczema trials are a bit of a mess, characterized by a profusion of poorly developed and unvalidated scales, making comparisons across studies difficult. Investigators should stick to using the core outcome sets recommended by the international HOME group (<http://www.homeforeczema.org/>).
- Some interventions (e.g., topical steroids and topical calcineurin inhibitors) are well supported by RCT evidence.
- For other interventions (such as Chinese herbs and house dust mite reduction), there is simply insufficient evidence to decide whether they are effective; better research is needed.
- In some areas (e.g., topical steroid–antibiotic combinations), the RCT evidence does not support a clinically useful effect – providing dermatologists and patients with an opportunity to disinvest in such treatments.
- In most people with mild to moderate atopic eczema, the condition can be easily controlled with a combination of emollients and topical corticosteroids for inflammatory flares.
- In those with more troublesome atopic eczema, proactive treatment with weekly topical corticosteroids or topical calcineurin inhibitors appears to have a large impact on prevention of flares.
- Cheap and well-established systemic agents such as oral steroids or azathioprine or methotrexate should be compared against each other in people with severe atopic eczema in large pragmatic trials.
- There is still room for more safe and effective treatments for severe atopic eczema.
- Trials exploring disease prevention need to be conducted for atopic eczema.
- Larger studies need to be conducted in order to explore subgroup differences for different subtypes of eczema – or example, patients who are atopic, those with associated asthma, and those with filaggrin gene mutations.

### **Acknowledgments**

Hywel Williams was responsible for writing the background and concluding sections and the evidence summaries on tacrolimus and pimecrolimus, as well as case scenario 24.3 summarizing systemic treatments, and for editing the other contributions in this chapter. Kim Thomas wrote the sections on emollients, Chinese herbal medicines, washing, clothing, and psychological interventions, washing. Jane Ravenscroft wrote the entire case scenario 24.2

section on infected eczema. Carolyn Charman wrote the section on topical steroids, and Helen Nankervis wrote the sections on antihistamines, house dust mite reduction, dietary exclusions, probiotics, and educational interventions. We wish to thank Sherie Smith for collating and ordering the references. Thanks also go to Masaki Futamura and Douglas Grindlay for developing and updating the Centre of Evidence-Based Dermatology map of all systematic reviews of eczema. We also wish to thank the NIHR Programme grants for Applied Research for supporting the work that led to the development of the GREAT database and the HOME initiative.

## CHAPTER 25

# Seborrheic dermatitis

Mauro Picardo and Norma Cameli

Laboratory of Cutaneous Physiopathology, San Gallicano Dermatological Institute (IRCCS), Elio Chianesi, Rome, Italy

## Background

### Definition

Seborrheic dermatitis is a chronic inflammatory skin disease characterized by erythematous and scaling plaques, with a distinctive distribution in scalp, eyebrows, nasolabial folds, retroauricular regions, sternum, and between the shoulder blades (Figure 25.1) [1], areas rich in sebaceous glands.

The relationship with “dandruff” is unclear; and this is a more generic term that refers to scalp flaking, regardless of etiology [2]. Pruritus of the scalp is often associated with the condition.

### Incidence/prevalence

There are two forms of seborrheic dermatitis: an infantile and an adult form. The former is self-limited and confined to the first 3 months of life, and the latter is chronic, peaking between the ages of 30 and 50 years. The prevalence of adult seborrheic dermatitis is estimated at 5% [3].

In a group of male adolescents (2201) in Brazil, the global prevalence of scalp seborrheic dermatitis has been found to be 11% and the occurrence was associated with higher body fat content [4].

In acquired immunodeficiency syndrome (AIDS) patients the incidence is increased (30–80%), probably related to CD4 levels (altered immune surveillance) [5].

Oble *et al.* have characterized an animal model which may mimic the seborrheic dermatitis in AIDS [6], implicating a fungal organism and CD4<sup>+</sup> T cell lymphopenia.

### Etiology/risk factors

The etiology is not clear, and several factors could play a major role: sebaceous gland secretions, individual susceptibility, and microfloral metabolism. Qualitative and quantitative abnormalities in the composition of sebum have been suggested, but not clearly defined. Dandruff and seborrheic dermatitis are chronic scalp manifestations probably with similar etiology, differing in severity. The manifestations are related to superficial stratum corneum disorders, including alterations of the epidermis with hyperproliferation, excess lipids, interdigitation of the corneal envelope, and parakeratosis [7]. The nonpathogenic fungus *Malassezia furfur* (*Pityrosporum ovale* and *Pityrosporum orbiculare*) may play a role [8], but the mechanism has not been completely clarified.

*Malassezia* strains are isolated more often from unhealthy scalps than from the scalps of normal individuals even though the total frequency is relatively low. However, several other fungal species have been isolated that are significantly different from those on healthy scalp, suggesting that the skin microbiome is modified during seborrheic dermatitis [9].

Investigations on the role of these pathogens have focused on their lipid metabolism. *Malassezia restricta* and *Malassezia globosa* require lipids and are capable of degrading sebum, releasing free fatty acids from triglycerides, consuming specific saturated fatty acids, and leaving behind the unsaturates. Penetration of the modified short fatty acids results in inflammation and irritation. The phospholipase activity, and particularly its induction after  $\beta$ -endorphin exposure, is a distinct metabolic trait of *Malassezia* strains isolated from lesional skin of seborrheic dermatitis patients, suggesting that the activity of this enzyme could be the target of additional research. The production of bioactive indoles such as *malessezin* has been related to the pathogenesis of the manifestation. The bioactive indoles are potent ligands of the aryl hydrocarbon receptor (AhR) expressed by keratinocytes and dendritic cells and are capable of inducing an inflammatory reaction and modulating the immune response [10].

Some studies have hypothesized that seborrheic dermatitis is related to altered immune response to *M. furfur*.

A transcriptomic analysis of scalp biopsies from individuals with dandruff/seborrheic dermatitis revealed more than 70 probes are differently regulated, with significant induction of inflammatory genes and proteins and conversely repressed lipid metabolism genes [11].

Increased keratinocyte and sebocyte turnover has been reported in association with altered keratinization. Systemic lipid metabolism and antioxidants may play a role in modulating the disease onset and the inflammatory reaction. A few studies have linked the onset or relapses with the patient's psychological condition, alcohol intake, psychotropic drugs, and a deficiency of micronutrients (lithium, zinc, magnesium, biotin).

### Prognosis

Although there are many treatments for seborrheic dermatitis, recurrences are very common, with the disease typically relapsing for years. Although the prognostic studies identified were not

Figure 25.1 A patient with seborrheic dermatitis.

long-term ones, preventive regimens have been developed to reduce the severity of the disease, including improvement in lifestyle, intake of supplements, and sun exposure.

### Aims

The aims of the treatment are to reduce symptoms and relapses with short-term treatment.

### Outcomes

No standard scales were found for the assessment of the severity of seborrheic dermatitis. Outcomes include the severity of symptoms (erythema, desquamation, itching), the rate of recurrence, the number of *P. orbiculare* colonies, patient satisfaction, and cosmetic acceptability.

### Search methods

Since few randomized controlled trials (RCTs) were found that met the criteria for clinical evidence, observational studies were included (up to September 2012).

## Questions

### What are the effects of topical treatment?

#### Antifungal agents

Topical antifungals are well established in the treatment of seborrheic dermatitis, and several clinical trials showed that different topical antifungal agents improve seborrheic dermatitis.

#### Efficacy

No systematic reviews were found.

**Ketoconazole** Seven double-blind placebo-controlled trials used cream or shampoo [12–18]. The largest trial, using 2% keto-

conazole shampoo ( $n = 575$ ) reported an excellent response in 88% of the patients treated. The treatment was effective in preventing relapses when used prophylactically once a week [12]. An RCT comparing 2% ketoconazole shampoo with 2.5% selenium sulfide shampoo found that ketoconazole was statistically superior to selenium sulfide ( $P = 0.0026$ ) and was better tolerated [13]. In two double-blind crossover studies ( $n = 20$  and  $n = 35$ ), the change in the clinical score with ketoconazole shampoo was significant ( $P < 0.01$ ) [14,15]. Two RCTs demonstrated the clinical efficacy of 2% cream in comparison with a placebo [16,17]. In a double-blind placebo-controlled trial, a gel containing a combination of 2% ketoconazole and 0.05% desonide was superior to the unmedicated gel [18].

One open, randomized, parallel study including a total of 66 patients showed that a 2% formulation was significantly more effective than a 1% formulation ( $P < 0.001$ ) and that the intermittent application of 2% ketoconazole shampoo can successfully prevent relapse [19].

The safety of 2% ketoconazole shampoo is supported by absorption studies and by local irritancy and contact sensitivity studies. Ketoconazole shampoo does not influence sebum production, but improves its delivery onto the skin surface [20].

**Bifonazole** We found three double-blind controlled trials and two open studies [21–23]. The largest, involving 100 patients, reported that 1% bifonazole cream was significantly better than placebo ( $P < 0.05$ ) [21].

**Ciclopiroxolamine** One placebo-controlled double-blind study of ciclopiroxolamine 1% cream in facial seborrheic dermatitis (57 patients in the ciclopiroxolamine group and 72 in the vehicle group) found a statistically significant difference ( $P < 0.01$ ) between the two treatment groups at the end of the initial phase (twice daily for 28 days) and in the maintenance phases (once daily for 28 days) [24].

We found five randomized, double-blind, vehicle-controlled trials of ciclopirox shampoo. In one study ( $n = 203$ ), the most pronounced improvement in the treatment of seborrheic dermatitis of the scalp was seen with ciclopirox 1% shampoo, in comparison with the lowest concentrations (0.1% and 0.3%) and the vehicle [25]. A trial ( $n = 183$ ) compared different application frequencies of 1% ciclopirox shampoo [26]. The most pronounced improvement was seen in the group treated three times a week and twice a week, in comparison with once a week and vehicle shampoo. Another study ( $n = 499$ ) reported that an effective treatment response was achieved in 26% of patients treated with ciclopirox in comparison with 12.9% of patients treated with the vehicle [27]. Vardy *et al.* ( $n = 102$ ) showed that the improvement of seborrheic dermatitis was significantly greater in a group treated with ciclopirox than in a group treated with placebo (93% and 41%, respectively) [28].

In a large study, 949 patients were randomly assigned to receive 1% ciclopirox shampoo once or twice weekly or vehicle for 4 weeks [29]. Ciclopirox once and twice weekly produced response rates of 57.9% and 45.4%, respectively, in comparison with 31.6% for the vehicle.

**Terbinafine** We found two RCTs: in one, the lesions cleared in 11 of 18 eligible patients after treatment with 1% terbinafine solution once daily for 4 weeks [30], while the other study

reported complete remission in 10 of 35 patients treated with 1% terbinafine cream [31].

**Other antifungals** Beneficial effects have been reported in open studies with fluconazole [32] and fenticonazole [33]. One study in a group of 30 men demonstrated that 0.2% octopirox in a shampoo vehicle was superior to the same level in the simple shampoo base and equivalent in activity to a much higher level (0.5%) in the base only [34].

#### **Drawbacks**

The few adverse effects reported include erythema, dryness, and pruritus.

#### **Comment**

The various antifungal drugs have not been compared. The possible mechanisms of action of these compounds include antifungal and anti-inflammatory effects.

#### **Zinc pyrithione**

A meta-analysis on nine different clinical trials confirmed a slight (20%) but significant improvement of symptoms with the use of a shampoo containing zinc pyrithione with no difference in the rate of the response among gender or ethnicity [35]. The transcriptome of dandruff/seborrheic dermatitis after treatment revealed that the treatment produced a profile resembling those of healthy scalp skin [11].

#### **Corticosteroids**

Recently, little information has been published on the use of topical steroids. The drugs, applied for 1–4 weeks, improve seborrheic dermatitis and do not cause systemic effects, but relapses are more frequent than with topical antifungals.

#### **Efficacy**

No systematic reviews were found. In one RCT, a 1% hydrocortisone solution was compared with miconazole and a combination of miconazole and hydrocortisone in 70 patients [36]; the combination was most effective. Recurrences were seen most frequently in the hydrocortisone group. We found one randomized double-blind controlled trial of 2% ketoconazole cream versus 0.05% clobetasol 17-butyrate cream [37], and one trial comparing topical application of 0.02% flumethasone pivalate with 2% eosin in 30 infants with seborrheic dermatitis; in the latter study, the two treatments were found to have comparable effects [38].

In an RCT study, clocortolone pivalate 0.1% cream was a more effective therapy than vehicle, and the patients had a low rate of adverse events [39].

#### **Drawbacks**

Long-term corticosteroid therapy may induce adverse effects, such as skin atrophy and telangiectasia.

#### **Comment**

No recent RCTs have demonstrated the efficacy of corticosteroids, although they are used as comparative drugs.

#### **Lithium succinate**

RCTs have found that lithium succinate improves seborrheic dermatitis in comparison with placebos.

#### **Efficacy**

We found two randomized, double-blind, placebo-controlled trials and one open trial with 8% lithium succinate ointment [40–42]. One crossover trial in nine centers (200 patients) and a parallel-group study in two centers (27 patients) showed that the symptom score improved significantly in the lithium group ( $P < 0.0001$ ) [40]. The other double-blind trial, conducted in 12 patients with AIDS-associated seborrheic dermatitis, reported rapid (2–5 days) and significant ( $P < 0.01$ ) clinical improvement in patients treated with lithium succinate [41].

#### **Drawbacks**

Adverse effects consisted of skin and eyelid irritation in a few patients.

#### **Comment**

Lithium inhibits growth in small colony strains of *Pityrosporum* and blocks the release of free fatty acids from tissue. Lithium also has potentially anti-inflammatory actions.

#### **Antibacterials**

We found only a few studies on metronidazole.

#### **Efficacy**

No systematic reviews were found. A double-blind study ( $n = 44$ ) described significant improvement after the use of 1% metronidazole gel in comparison with a placebo for 8 weeks. Fourteen patients in the metronidazole group and two in the placebo group had complete improvement [43].

#### **Drawbacks**

None reported. Metronidazole gel was well tolerated and did not produce adverse effects.

#### **Comment**

The mechanism of action of metronidazole is not known.

#### **Benzoyl peroxide**

Two controlled studies have reported on the efficacy of benzoyl peroxide.

#### **Efficacy**

Of the two studies, one open trial noted improvement in 28 of 30 patients treated for several months with 2.5% benzoyl peroxide [44]. The second, a double-blind RCT including 59 patients, compared 5% benzoyl peroxide with placebo for 4 weeks and reported a significant improvement in erythema, pruritus, and scaling in the group treated with benzoyl peroxide ( $P < 0.05$ ) [45].

#### **Drawbacks**

Skin irritation was reported as a side effect.

#### **Propylene glycol**

We found one double-blind controlled study, in which 39 patients with seborrheic dermatitis of the scalp were treated with a solution containing 15% propylene glycol [46]. The lesions improved in 89% of the patients treated with propylene glycol, in comparison with 32% in the placebo group. In vitro, the *P. orbiculare* counts were reduced significantly after treatment with propylene glycol, but not in the placebo group.

## Pimecrolimus

RCTs have found that pimecrolimus cream 1% improves seborrheic dermatitis.

### Efficacy

In one study ( $n = 19$ ), 1% pimecrolimus cream was applied as monotherapy twice daily for 7 days and for an additional period of 7 days until complete clearance was achieved [47]; 52% of patients reached complete clearance.

We found one open-label clinical trial conducted in 20 patients – 11 patients in the 1% pimecrolimus cream group and nine patients in the betamethasone 17-valerate 0.1% cream group [48]. Both agents were highly effective in the treatment of seborrheic dermatitis. More severe and frequent relapses were observed with betamethasone than with pimecrolimus.

### Drawbacks

Rosaceaform dermatitis is an adverse side effect complicating treatment with 1% pimecrolimus cream [49].

### Comment

Pimecrolimus is a calcineurin inhibitor that has been successfully used in inflammatory skin diseases. It selectively targets T cells and mast cells and inhibits T cell proliferation and the production and release of interleukin-2, interleukin-4, interferon gamma, and tumor necrosis factor- $\alpha$ . In contrast to corticosteroids, pimecrolimus does not induce skin atrophy.

## Miscellaneous

Several treatments have been claimed to be effective in uncontrolled studies. A blind, randomized, parallel-group study in 80 patients found that 1% ichthylol (ichthammol) was superior to 4% coal tar in seborrheic dermatitis of the scalp [50].

Tacalcitol (1 $\alpha$ ,24-dihydroxycholecalciferol) was used in four patients, with good results [51]; crude honey (30 patients) [52], borage oil, 40% urea ointment [53], dithranol (18 patients) [54], pyridoxine, and cystine [55] have been reported to be beneficial in uncontrolled studies.

## Ultraviolet light

RCTs have found that phototherapy improves seborrheic dermatitis.

### Efficacy

No systematic reviews were found. Limited evidence suggests that natural sunlight has a significant effect on seborrheic dermatitis [56,57]. One RCT ( $n = 48$ ) found improvement in 85% of patients receiving selective ultraviolet phototherapy, and in 76% of patients treated with psoralen–ultraviolet A after a mean of 26 treatments [58]. In an open study, 18 patients with severe seborrheic dermatitis were treated with narrowband ultraviolet B (UVB; TL-01) phototherapy, three times weekly, starting with 70% of the minimal erythema dose up to a maximum of 8 weeks. All patients responded to narrowband UVB. Twelve completed the study; six had complete remission and six had marked improvement [59].

### Drawbacks

No side effects were reported, except for rare episodes of moderate erythema.

### Comment

The trials of phototherapy were too few for its effectiveness to be evaluated.

## What are the effects of systemic treatments?

### Antifungal drugs

We found limited evidence that oral antifungals are beneficial.

### Efficacy

We found no systematic reviews.

**Ketoconazole** One double-blind placebo-controlled crossover study in 19 patients compared ketoconazole 200 mg/day for 4 weeks with placebo. Seventy percent of the patients showed significantly greater improvement with ketoconazole, particularly on the scalp, in comparison with 10% with placebo ( $P < 0.01$ ) [60].

**Terbinafine** In one placebo-controlled trial ( $n = 60$ ), oral terbinafine 250 mg once daily for 4 weeks significantly reduced scores ( $P < 0.0001$ ) in comparison with the baseline and with control groups [61].

In a randomized, double-blind, placebo-controlled study ( $n = 174$ ) in patients with lesions in nonexposed sites and in patients with lesions in exposed skin areas, oral terbinafine (250 mg/day) or a placebo were each administered for 6 weeks [62]. In patients with lesions in nonexposed sites, the response rate was significantly higher with terbinafine (70% vs 45.4%;  $P = 0.03$ ). No significant differences were reported in patients in exposed skin areas.

**Itraconazole** We found two RCTs of oral itraconazole. In one ( $n = 32$ ), the treatment was given in two different periods. In the first period, 1% hydrocortisone cream was administered for 4 weeks and 200 mg itraconazole daily during the first week; in the second period, the cream was discontinued and itraconazole was given on the first 2 days of every month for 11 months [63]. Nineteen patients showed significant improvement or complete recovery, six had moderate improvement, and three had slight improvement. In an open, noncomparative trial ( $n = 29$ ), itraconazole 100 mg was given twice a day for 1 week and then, after a 3-week interval, for the first 2 days of the following 2 months [64]. Clinical improvement was observed in 23 patients. In another study itraconazole was given to 30 patients in a dose of 100 mg twice daily for 1 week followed by 200 mg/day for first 2 days of the following 2 months. Clinical improvement was observed in 83.3% cases [65].

### Drawbacks

Ketoconazole damages the liver and interferes with testosterone metabolism. No side effects were reported during the terbinafine studies.

### Comment

Seborrheic dermatitis relapses when the drugs are stopped, so that prolonged treatment is often needed. Systemic antifungal drugs are not suitable for this.

## What are the effects of nutrients?

We found no controlled studies of the effects of nutrients, vitamins, and trace elements on seborrheic dermatitis. On the basis of limited

observational evidence, seborrheic dermatitis is said to have improved after administration of vitamins A, E, D, B<sub>1</sub>, B<sub>2</sub>, B<sub>6</sub>, and C, niacin, biotin, selenium, zinc, or iron [66,67].

## Do treatments that reduce sebaceous secretions improve the symptoms?

### Retinoids and antiandrogens

We found that few drugs interfere with sebum secretion, and there is insufficient evidence that controlling sebum production leads to improvement of seborrheic dermatitis.

### Efficacy

Oral retinoids reduce sebaceous gland size, suppress sebum production, and inhibit sebocyte differentiation; they also have anti-inflammatory activity [68]. Antiandrogen and 5- $\alpha$ -reductase inhibitors reduce the size of the sebaceous glandular lobules and ducts [69].

We found no evidence to support the hypothesis that reducing sebum production decreases the probability of developing seborrheic dermatitis.

### Key points

- RCTs show that topical antifungal treatment and metronidazole are effective.
- Limited evidence suggests that systemic antifungal therapy can be useful in controlling the disease.
- Few RCTs have examined the efficacy of topical steroids.
- We found limited or no evidence on the effect of natural sunlight and/or systemic nutrients.

## Background

### Definition

Psoriasis is an inflammatory disease of the skin characterized by an accelerated rate of epidermal turnover, with hyperproliferation and defective maturation of epidermal keratinocytes. In the majority of cases psoriasis is a chronic disease, which in its most common form – chronic plaque psoriasis – manifests as well-demarcated, often symmetrically distributed, thickened, red, scaly plaques. These may vary considerably both in size and in number and may involve any part of the skin, although they are found most typically on the extensor surfaces of the knees and elbows, in the sacral area, and in the scalp. Appearances may be modified by the site of involvement, with flexural areas showing beef-red shiny plaques without scale (flexural or inverse psoriasis), palms and soles showing marked hyperkeratosis and fissuring, and nails becoming distorted by thimble-pits, thickening, and nail-plate detachment. Up to 8% of individuals with psoriasis may have an associated inflammatory arthropathy [1], which in severe cases may be the dominant cause of morbidity.

Acute inflammatory forms of psoriasis may develop *de novo*, or may complicate existing chronic plaque psoriasis. Acute guttate psoriasis characteristically affects children and young adults following streptococcal infection [2]. Typically, showers of tiny red papules (likened to raindrops or guttate) erupt over large areas of the skin surface 1–2 weeks after an episode of acute streptococcal pharyngitis or tonsillitis. Erythrodermic and generalized pustular psoriasis are uncommon but severe and potentially life-threatening forms of psoriasis, which may be complicated by high-output cardiac failure, temperature dysregulation, and septicemia, particularly in the elderly.

Psoriasis is associated with two relatively uncommon conditions that may cause long-lasting disability as a result of severe inflammation and pustulation affecting the hands and feet. The first is now more commonly referred to as palmoplantar pustulosis, but is still widely known as chronic palmoplantar pustular psoriasis. Although

associated with psoriasis elsewhere in about one-fifth of cases, it is now considered to be a genetically separate entity [3]. Acropustulosis (acrodermatitis continua of Hallopeau), on the other hand, may be associated with generalized pustular psoriasis [3]. The relationship of these two conditions to psoriasis vulgaris remains poorly understood.

### Prevalence

Psoriasis affects 1–3% of the general population. It is believed to be less frequent in some ethnic groups (e.g., in people from West Africa and China), but we have found no reliable epidemiological data to support this [4].

### Etiology

Epidermal turnover is greatly accelerated in psoriasis, such that keratinocytes within active psoriatic plaques may travel from the basal layer of the epidermis to the stratum corneum in as little as 4 days, rather than the normal 28 days. Exactly what drives this process is incompletely understood, but it is agreed that it is mediated by activated T lymphocytes and that there is a strong genetic component [5]. Physical trauma, acute infection, and some medications (e.g., lithium and beta-blockers) are believed to trigger the condition. A few observational studies have linked the onset or relapse of psoriasis with stressful life events and personal habits, including cigarette smoking and, less consistently, alcohol consumption. An association of psoriasis with body mass index is also well documented [4].

### Prognosis

Psoriasis is known to last years or decades and to be subject to periods of remission and relapse. We did not, however, find any long-term studies examining the prognosis. There is growing evidence that moderate to severe psoriasis is associated with a significantly increased risk of cardiovascular morbidity [6,7], with at least double the prevalence of obesity, type 2 diabetes, arterial hypertension, hyperlipidemia, and coronary heart disease [7]. The odds of having the metabolic syndrome, a defined combination of these conditions, were found to be more than five times higher amongst 581 adult patients hospitalized for severe psoriasis than in a control group of hospitalized patients (odds ratio [OR], 5.29) [7]. Psoriasis

<sup>1</sup>Based on Chapter 21 from the second edition by Luigi Naldi and Robert J.G. Chalmers.

may substantially affect quality of life, by influencing a negative body image and self-image and limiting daily activities, social contacts, and work. One systematic review (search date 2000, 17 cohort studies) confirmed that severe psoriasis is associated with lower levels of quality of life than mild psoriasis [8]. At present, there is no cure for psoriasis. However, in many people it can be well controlled with treatment, at least in the short term.

### Aims of treatment

Until there is a safe and effective cure for psoriasis, a balance needs to be struck between patients' individual perceptions of disability from psoriasis, their willingness to devote time and effort to managing the disease, and their preparedness to accept risks from treatment.

In a European consensus group, treatment goals have been defined to give guidance on the assessment of a treatment success. According to the consensus group, a treatment can be considered a success and should be continued as a maintenance therapy if the improvement of the psoriasis area and severity index (PASI) is equal to or more than 75% within a time period of 16–24 weeks. Treatment regime should be modified if improvement of PASI is less than 50%. In a situation where the therapeutic response improved by equal to or more than 50% but by less than 75% as assessed by PASI, the therapy should be modified if the dermatology life quality index (DLQI) is  $>5$  but can be continued if the DLQI  $\leq 5$  [9].

### Relevant outcomes

Outcomes should reflect the aims stated above: efficacy as measured by many different outcome measures like PASI, physician global assessment (PGA), or some other objective disease activity score, disease-related quality of life; patient satisfaction and autonomy, clearance or improvement of psoriasis over time; acceptability to patients of treatment regimens; duration of remission; and adverse effects of treatment, number of drop outs due to side effects, management and control of comorbidities. Harmonizing outcome measures used in clinical studies and practice may improve the comparability of treatments in the future (<http://www.comet-initiative.org>).

### Methods of search

This chapter uses information extracted from different systematic reviews and evidence-based guidelines. It was generally attempted to use information from the most recent sources available. The sources used are stated at the beginning of the individual section. In some cases, additional important trials published after the deadline of the cited reviews were added. The description of "harms" is done by means of a narrative selection of information derived from the guidelines and additional clinical trials. Very rare adverse events are not likely to have been identified in clinical trials.

## Topical treatment of chronic plaque-type psoriasis

### How effective are different topical treatments for chronic plaque-type psoriasis?

#### Sources of information

- 8, 2012, Medline, Embase, Cochrane, Cumulative Index to Nursing and Allied Health Literature (CINAHL)) [10];
- S3 – Guidelines for the treatment of psoriasis vulgaris: update 2011 (search date November 2009, Medline, Embase, Cochrane) [11];
- Cochrane review on topical treatments for chronic plaque psoriasis 2009 (search date 2005, Medline, Embase, Science Citation Index, Biosis, Dissertation Abstracts, Inside Conferences; SIGLE; National Research Register, metaRegister of Current Controlled Trials) [12];
- Menter *et al.*: Guidelines of care for the management of psoriasis and psoriatic arthritis. Section 3. Guidelines of care for the management and treatment of psoriasis with topical therapies (search date 2008, Medline) [13].

### Calcineurin inhibitors

#### Benefit

**Global estimate of efficacy** In 40–50% of patients tacrolimus shows a significant improvement or complete clearance after 6–12 weeks. Pimecrolimus has not been studied in a randomized controlled trial (RCT) in chronic plaque-type psoriasis [11].

**Different dosages of calcineurin inhibitors** Tacrolimus 0.1% ointment is the most commonly used concentration and is preferable in psoriasis [11–13]. One psoriasis study applied tacrolimus 0.3% gel and one used a 0.5% cream. Tacrolimus 0.03% ointment has not been studied in RCTs in psoriasis.

**Tacrolimus versus placebo** There are no true placebo-controlled trials for tacrolimus ointment in psoriasis. In one trial, the combination of topical tacrolimus 0.1% plus 6% salicylic acid gel is compared with salicylic acid gel alone demonstrating an improvement of at least 75% in 11/24 patients compared with 4/24 in the control group [11].

**Calcineurin inhibitors versus vitamin D analogues** Two trials compared topical tacrolimus with calcipotriol. In the first study, tacrolimus 0.3% gel and 0.5% cream and calcipotriol were equally effective (about 45% had a PGA of "much better") [11]. In a second study, 50 patients with facial and anogenital chronic plaque-type psoriasis, 60% of patients in the tacrolimus group were completely clear compared with 33% in the calcipotriol group. The Cochrane review by Mason *et al.* demonstrated no significant difference between tacrolimus and vitamin D3 derivatives (mean,  $-0.04$  [ $-0.53, +0.61$ ]) [12].

**Calcineurin inhibitors in combination therapy** There are no RCT studies on combination therapy in chronic plaque-type psoriasis with other topical or systemic therapies. Combination therapy with ultraviolet (UV) therapy should be avoided because of a potential carcinogenic effect.

#### Harms

It should be noted that all information available is derived from their use in atopic dermatitis. Most people experience a burning sensation immediately after applying tacrolimus and to a lesser extent for pimecrolimus, which often diminishes after a couple of days [11–13]. Application of a topical corticosteroid (TC) may reduce the burning sensation. The immunosuppressive effects of calcineurin inhibitors (CNIs) leads to an increased risk of bacterial and viral skin infections (e.g., folliculitis, warts, herpes simplex). A

combination with UV therapy (or excessive sunlight exposure) should be avoided because animal models have suggested an increased risk of cutaneous malignancies [11–13]. No data are available on the carcinogenic effect of CNIs in humans, but both CNIs have a “black box” warning [13]. Although there are no reports on birth defects related to exposure to CNIs, use of this drug class during pregnancy should be avoided. There are no known drug interactions.

### Comments

Topical tacrolimus (or pimecrolimus) is not the first-line treatment for chronic plaque-type psoriasis, but may be considered for facial, intertriginous, and anogenital regions because of adverse effects of corticosteroids and vitamin D analogues [11–13]. Since tacrolimus ointment is off label for psoriasis, it is recommended to document its use carefully. The tacrolimus 0.1% ointment is preferable, but its vehicle may not be cosmetically acceptable for patients.

### Dithranol

Throughout this section, the individual studies referred to can be found in Refs [11–13].

### Benefit

**Global estimate of efficacy** The response rate (significant improvement or complete clearance) for dithranol varies greatly between 30 and 70% (evidence level 2) [11,13].

**Different dosages of dithranol** Outpatient treatment is preferably performed with short-contact therapy. A 1% cream is applied for 10 min once daily and gradually the duration of contact is increased up to 30 min after which the concentration can be increased up to 3% [11]. The cream should be rinsed off without soap using lukewarm water. “Classical” dithranol therapy begins with 0.1% ointment twice daily without washing it off. Depending on the level of irritation, the concentration is doubled every 3 days up to 1–3%.

**Dithranol versus placebo** In the two small placebo-controlled studies of the efficacy of dithranol as monotherapy for 12 and 27 patients, a totally aqueous gel formulation of dithranol in increasing concentrations as tolerated up to as high as 2% applied twice daily for 4 weeks, and a 1 min treatment with 2% dithranol ointment daily for 3 weeks both demonstrated significantly better results than placebo in the treatment of psoriasis [13]. The Cochrane review by Mason *et al.* included three studies on topical therapy of psoriasis vulgaris with dithranol [12]. With a 95% confidence interval (CI) of –0.46 to –1.65 the mean (standardized weighted mean difference) for comparison of efficacies of verum versus placebo is at –1.05, clearly in the significant range, and thus is evidence of the efficacy of local dithranol therapy.

**Classic dithranol versus short contact** The available data failed to show the superiority of classic therapy over short-contact therapy [11]. Moreover, the modern preparation was equally effective compared with the traditional dithranol preparations [11].

**Dithranol versus vitamin D analogues** Monastrili *et al.* showed that each of the 23 patients using short-contact dithranol therapy reached PASI 75, but none of the patients achieved PASI 100 after 6 weeks. However, adding calcipotriol twice daily to this regimen resulted in complete clearance of all patients in the comparative arm. Van de Kerkhof *et al.* showed that short-contact dithranol was

superior to calcipotriol after 12 weeks (63.8% vs 58.5% PASI reduction), but not after 4 weeks [11].

The Cochrane review by Mason *et al.* demonstrated no significant difference between dithranol and vitamin D3 derivatives (mean, –0.04 [–0.53, +0.61]) [12].

**Dithranol versus topical steroids** One trial compared dithranol monotherapy with clobetasol and a combination of both. Each monotherapy resulted in a remission of 80% and the combination therapy in complete remission of all treated plaques [11,13].

**Dithranol in combination therapy** As mentioned above, dithranol can effectively be combined with calcipotriol and topical steroids. Its combination with phototherapy will be discussed in that section.

### Harms

The most common adverse effects are redness and burning of (peri) lesional skin and guide the increment of contact duration and concentration. Brown discoloration of the skin, nails, hair, and clothing can occur. The discoloration of the skin usually persists for 4–6 weeks. These side effects can be prevented by using glove when applying the drug, avoiding use of dithranol on the face (and intertriginous areas), protecting the surrounding skin (e.g., zinc paste), or by applying topical steroids. Nevertheless, these cosmetic adverse effects have decreased the use of dithranol over the years.

Blistering and necroses may occur due to overdoses. Very rarely a contact allergy can develop.

Although there are no reports on birth defects related to dithranol exposure, use of dithranol should be restricted to small areas (<30% of body surface area (BSA)) during pregnancy. During nursing it should not be applied on the breasts. There are no known drug interactions.

### Comments

The feasibility of dithranol in an outpatient setting is limited because of side effects, but it is effective in day-care centers or during hospitalization and can be combined with other topical drugs or UV therapy.

### Topical corticosteroids

Throughout this section, the individual studies referred to can be found in Refs [11–13].

### Benefit

**Global estimate of efficacy** The proportion of psoriasis patients with a significant improvement or complete clearance depends on the type, dosage, and duration of use of TC. For topical bethamethasone dipropionate, 46–56% of patients show at least a marked improvement [11,13].

**Different types and dosages of topical corticosteroids** The dosage and treatment duration of TCs depend on the preparation (Class I–IV). Basically, TCs are applied daily at the affected site and after a satisfying response are tapered down. Typically, TCs are applied once daily for 3 weeks after which it is tapered down to once very other day over a period of 1–2 weeks or restricted during three consecutive days a week [10,11,13]. Most of the studies assess TC ointment, but several studies have investigated other galenic forms of TC.

For bethamethasone dipropionate, mometasone furoate or clobetasol 17-propionate, there are no eligible studies directly comparing the efficacy of once versus twice daily [11,13].

**Different topical corticosteroids versus placebo** Treatment success of bethamethasone dipropionate 0.05 mg/g (class III TC) has been demonstrated in almost a dozen trials after 2–6 weeks of use. Two large RCTs by Douglas *et al.* and Papp *et al.* reported significant improvement or complete clearance within 4 weeks in 46% and 56%, respectively, using bethamethasone dipropionate ointment twice daily. In a study by Kaufman *et al.*, 37% of patients treated with topical bethamethasone dipropionate once daily responded successfully. The Cochrane review included studies on bethamethasone dipropionate and showed a mean of  $-1.00$  (95% CI,  $-0.32$ ,  $-1.68$ ), demonstrating a large and significant effect compared with placebo.

Of the four eligible studies on mometasone furoate ointment, which is also a class III TC, one was placebo controlled and showed a good efficacy of this drug in chronic plaque psoriasis [11,13]. A study by Peharda *et al.* showed that once-daily application resulted in 64% of patients in a 75% improvement. Two studies examined the effect of mometasone furoate twice daily showing 50% or more improvement in 68% and 77% of patients [11]. The meta-analysis of the Cochrane review showed a mean of  $-0.75$ , indicating the effect of mometasone furoate is clearly significant.

Eleven studies were included that showed significant efficacy of monotherapy of clobetasol 17-propionate (class IV TC) resulting in a mean of  $-1.24$  (95% CI,  $-0.98$ ,  $-1.50$ ) [11–13]. Nine of the 11 trials applied this drug twice daily. The drug can be administered in different galenics. Twice-daily clobetasol 17-propionate ointment was effective in 89% of patients after 2 weeks. Two studies comparing the efficacy of cream versus lotion showed little difference. For example, Decroix *et al.* reported significant improvement or complete clearance after 4 weeks in 78% (cream), 75% (lotion), and 15% (placebo). Use of a foam preparation was successful in 27% of patients after 2 weeks in one study, but in 68% in another study. Menter *et al.* reported that a clobetasol 17-propionate spray twice daily resulted in a (near) complete clearance in 75% of patients. In summary, ointment appears to be the most effective, and it remains impossible to differentiate between cream, lotion, foam, and spray on the available evidence [11,13].

One small study compared the efficacy of class III versus IV corticosteroids: 89% of patients using clobetasol 17-propionate and 78% of patients using bethamethasone dipropionate had 75% or more improvement. In the Mason *et al.* review [12], class IV corticosteroids were superior to class III steroids.

**Topical corticosteroids versus vitamin D3 analogues** See under calcipotriol.

**Topical corticosteroids in combination therapy** Two studies compared TCs with or without salicylic acid. Katz *et al.* showed that adding 5% salicylic acid to mometasone furoate ointment increased the response rate from 77% to 86% [11,13]. Similarly, bethamethasone dipropionate plus salicylic acid was more effective than bethamethasone dipropionate ointment alone (53% vs 36%) because of enhanced penetration of the TC.

### Harms

The risk of adverse events and their frequency depends on the potency of the TC, site of application, and duration of use [10–13]. Long-term use of a potent TC results in atrophy, but this may be less of a concern in psoriasis than in other skin conditions, and moderate-strength TCs (e.g., triamcinolone acetonide and mometasone) can be tolerated over a longer period of time. Atrophy is a

special concern for continuous use of (very) potent TCs on the face and intertriginous areas and to a lesser extent on the remaining body, and is of relatively little concern on the palms, soles, and scalp. In general, it is recommended to use potent and very potent TCs for no longer than 4 and 8 weeks continuously [10]. Application of TC may increase the risk of superinfection, especially in the intertriginous region. On the face, TC application can provoke steroid acne, rosacea, and perioral dermatitis [10,11,13].

Rare, but possible systemic effects are Cushing syndrome, osteonecrosis, growth retardation, cataracts, glaucoma, and suppression of the hypothalamic–pituitary–adrenal axis [13]. The greatest risk of systemic effects occurs when very potent TCs are used over a large surface for a prolonged period of time and/or are used under occlusion [13]. Of the very potent TCs, less than 50 g per week should be used [13].

The use of TCs has not been associated with birth defects. However, prolonged use of TCs applied over large areas may affect the growth of the fetus and induce adrenal cortex atrophy. TCs are secreted in the breast milk. There are no known drug interactions.

### Comments

TCs remain the cornerstone in the topical treatment of psoriasis. Both class III and IV are very effective in inducing remission, but class IV appears superior. Mild TCs are recommended for psoriasis in the face and intertriginous areas and in infants and children. It remains unclear whether once- or twice-daily is recommended, but the frequency as well as duration should be tapered down in a maintenance phase because long-term use of TCs may lead to cutaneous and systemic adverse effects. Of these side effects, skin atrophy is the most common, but seems less of an issue in patients with psoriasis than in patients with other skin diseases, such as atopic dermatitis. Nevertheless, be aware that continuous use of (very) potent steroids may cause irreversible skin atrophy and striae, cause psoriasis to become unstable, and has systemic effects if used on large surfaces. The ointment vehicle appears most effective, but there are a variety of galenic forms to increase feasibility and treatment adherence if needed without losing too much efficacy [13]. The choice among the different galenics depends on disease severity, localization of psoriasis, patient preference, and costs [10,11,13].

### Coal tar

Throughout this section, the individual studies referred to can be found in Refs [11–13].

### Benefit

**Global estimate of efficacy** There are insufficient data for assessing response rate to monotherapy with coal tar [11].

**Different dosages of coal tar** In the included psoriasis trials, coal tar was applied as an ointment in 5% concentration. The “Goeckermann scheme” is application of coal tar for 1 h or more followed by UVB after removing the tar preparation.

**Coal tar versus placebo** One of six eligible studies compared monotherapy liquor carbonis detergens preparation to base showing basically no difference (48% vs 35% response rate after 4 weeks) [11]. In the pooled analyses, monotherapy of coal tar was not considered superior to placebo (mean,  $-0.48$ ; 95% CI,  $-1.15$ ,  $+0.18$ ) [12].

**Coal tar versus vitamin D3 derivatives** On the basis of two small studies, pooling of data demonstrated that calcipotriol monotherapy was significantly superior to coal tar (mean,  $-1.13$ ; 95% CI,  $-1.60, -0.67$ ) [11,12].

**Coal tar in combination therapy** Coal tar followed by UVB therapy has been studied in six small studies with various designs (UVB frequency, duration of contact, bilateral comparisons) and most frequently including hospitalized patients. This combination therapy seemed effective, but it ranged from 41% to 100% and was not always statistically superior to placebo ointment [11].

A study by Pinheiro *et al.* showed that only 49% of patients had a significant improvement or clearance using a combination of 5% coal tar, 2% allantoin and 0.5% hydrocortisone compared with 72% using calcipotriol monotherapy [11,13].

### Harms

The most common side effect is the brown staining of the skin and clothing and an unpleasant odor. In combination with UV exposure, coal tar can induce solar dermatitis due to photosensitization [11]. Coal tar is carcinogenic in humans (e.g., genital cancer) and various animal models [10–13]. Therefore, coal tar is contraindicated in patients with genodermatoses associated with skin cancer, and a history of skin cancer is a relative contraindication. Coal tar products are contraindicated in pregnant and nursing women.

### Comments

Based on the available literature, coal tar monotherapy is not recommended for the therapy of chronic plaque-type psoriasis. In combination with UV therapy, it may be considered in individual patients in day-care settings or during hospitalization. The uncertainty of its carcinogenic effects during skin therapy, its staining, and odor decrease its acceptance by patients.

### Tazarotene

Throughout this section, the individual studies referred to can be found in Refs [11–13].

### Benefit

**Global estimate of efficacy** About half the patients show 50% improvement using 0.1% tazarotene gel after 12 weeks [11,13].

**Different dosages of tazarotene** Tazarotene gel 0.1% is applied once daily, preferable in the evening, to the affected sites only ( $<10\%$  BSA).

**Tazarotene versus placebo** In the German guideline, seven psoriasis studies assessing tazarotene monotherapy were eligible [11]. Weinstein *et al.* showed that 59% of patients treated with tazarotene 0.1% cream, 48% of those treated with tazarotene 0.05% cream, and 26% of placebo-treated patients had at least an improvement of 50% [11]. The difference between tazarotene 0.1% and 0.05% cream was not statistically different. Gollnick and Menter reported 80% of patients showed a similar improvement using 0.1% tazarotene gel after 12 weeks. However, Green *et al.* reported the same result for only 35% of patients using 0.1% tazarotene gel. In the pooled analyses done by Mason *et al.*, monotherapy of tazarotene was superior to placebo [12].

No studies were included that compared tazarotene with other active topical agents.

**Tazarotene in combination therapy** Green and Sadoff compared various combinations of tazarotene and TCs and best results were achieved with tazarotene plus bethamethasone dipropionate or mometasone cream (78% and 66%, respectively, had 50% improvement) [11,13]. Tazarotene and mometasone ointment in the morning and tazarotene in the evening resulted in a 50% improvement in 83% of patients. Another study suggested an increase in efficacy from 81% to 95% from combining tazarotene with low- to high-potency TCs.

### Harms

Topical tazarotene frequently causes dose-dependent skin irritation, such as itching, burning, and redness. To reduce this tazarotene-induced skin irritation it is often combined with a TC [11,13]. Moreover, tazarotene should not be combined with other topical irritative therapies. Tazarotene may be photosensitizing due to thinning of the epidermis. Long-term use over large areas may result in side effects observed in oral retinoid use [11,13]. Oral tazarotene causes birth defects in mice, and topical application in humans has led to fetal skeletal changes. It is passed on through breast milk.

### Comments

Although tazarotene 0.1% gel once daily can be quite effective in the treatment of localized psoriasis, its use is restricted by the induced skin irritation. To reduce skin irritation, combination therapy with a TC can be indicated.

### Vitamin D analogues

Throughout this section, the individual studies referred to can be found in Refs [11–13].

### Benefit

**Global estimate of efficacy** Between 30 and 50% of patients experience significant improvement or complete clearance after 4–6 weeks use of vitamin D analogues [11,13].

**Different dosages of vitamin D analogues** Calcipotriol and calcitriol can be used once or twice daily in the initial and maintenance phases, whereas tacalcitol is recommended to be used once daily [11]. The maximum of affected skin treated with vitamin D analogues is 30%, 35%, and 20% for calcipotriol, calcitriol, and tacalcitol, respectively [11,13]. Calcipotriol is available in a cream and lotion (no longer in an ointment) and calcitriol and tacalcitol in an ointment.

**Vitamin D analogues versus placebo** The Cochrane review included 15 studies on calcipotriol versus placebo and confirmed a significant effect of calcipotriol with a mean  $-1.02$  (95% CI,  $-0.83, -1.21$ ) [12]. Three large and high-quality studies reported that between 33.4% and 50.7% of patients had a marked improvement and/or were clear after twice-daily application of calcipotriol [11,13]. This response rate further increased up to 74% if duration of use was extended up to 8–12 weeks. Calcipotriol solution was successful in 60% of patients with scalp psoriasis compared with 17% of placebo patients [13]. There are no direct comparative studies of once- versus twice-daily calcipotriol, but once seems less effective than twice daily [11].

In the German guidelines, five studies evaluating calcitriol met the eligibility criteria [11]. Camarasa *et al.* showed a significant improvement or clearance in 52% of patients and Hutchinson in

32% of patients after applying calcitriol twice daily. However, the Cochrane review failed to show that calcitriol was statistically superior to placebo (mean,  $-1.03$ ; 95% CI,  $-2.25, +0.19$ ) [12].

One tacalcitol study showed that 18% and 25% of patients were successfully treated after 4 weeks and 6 weeks, respectively [11,13]. The pooled analysis of three studies suggested that tacalcitol was significantly more effective than placebo (mean,  $-0.82$ ; 95% CI,  $-1.34, -0.29$ ) [12].

**Comparative studies with drug class** A study by Zhu *et al.* showed no significant difference in clinical response between calcipotriol and calcitriol, which was confirmed by the pooled analysis in the Cochrane review [11–13]. On the basis of one large study, calcipotriol appeared more effective than tacalcitol (22% vs 18% of patients achieved a significant response and/or were clear after 4 weeks) [11,13]. The superiority of calcipotriol over tacalcitol was confirmed in the Cochrane review (mean,  $-0.47$ ; 95% CI,  $-0.21, -0.73$ ) [12]. There are no direct comparative studies between calcitriol and tacalcitol.

**Calcipotriol versus tacrolimus** One study by Ortonne *et al.* showed that comparable proportion of patients using calcipotriol and tacrolimus scored “much better” on the PGA after 12 weeks (48.6% vs 44.4%) [11].

**Calcipotriol versus class III steroid** Four studies compared the efficacy of (once or twice) daily calcipotriol and class III steroids showing that the topical steroids were significantly more effective (difference between drugs was between 7.7% and 22.4% in favor of the steroids) [11]. The Cochrane review included nine studies and demonstrated a slight, but not significant, advantage for steroid therapy of 0.19 (95% CI,  $-0.17, +0.55$ ) [12].

**Calcipotriol versus dithranol** Van de Kerkhof *et al.* have shown in two studies that calcipotriol was more significantly effective and had a more rapid response than dithranol cream in the first month [11,13]. However, after 12 weeks the therapeutic success was slightly higher for dithranol compared with calcipotriol (63.8% vs 59.8%). However, a pooled analysis of five studies suggested that dithranol and calcipotriol were equally effective (mean,  $-0.01$ ; 95% CI,  $-0.71, +0.69$ ) [12].

**Vitamin D analogues in combination therapy** In the German guideline, 20 studies were included that assessed the efficacy of vitamin D analogues in combination with topical and/or systemic therapy [11]. The combination can be categorized in topical combination therapy: combination drugs in one preparation (in ointment or gel) and sequential therapy [11]. Twelve studies evaluated the combination therapy of calcitriol and bethamethasone dipropionate once or twice daily. The advantage of this combination is to reduce the skin irritation induced by calcipotriol, and it may have a corticosteroid-sparing effect as well. After 4 weeks of therapy, 45–63.3% of patients responded well to this combination drug once daily [11,13]. Increasing the frequency of application to twice daily increased the efficacy up to 68.0–76.1% of patients in three large and high-quality studies. The Cochrane review confirmed the superiority of twice-daily therapy of calcitriol and bethamethasone dipropionate to once daily (mean, 0.67; 95% CI, 0.36, 0.97). In the first month, the combination drug is more effective than each of the components separately in multiple studies with large numbers of patients. Several studies investigated the maintenance therapy

following a 4-week induction therapy with the combination drug and suggested that continued use of the combination drug is more effective in reducing the mean PASI than calcipotriol monotherapy in the maintenance phase [11]. Two large studies showed that the combination drug in a gel formulation was effective in 68% of patients with scalp psoriasis and was superior to calcipotriol solution ( $<45\%$  in both studies) [11]. Combination therapy with clobetasol and calcipotriol is also superior to calcipotriol monotherapy (mean, 0.60; 95% CI, 0.18, 1.02) [11].

Combination use of calcipotriol with salicylic acid or dithranol may diminish the effectiveness of calcipotriol and is, therefore, not recommended. Tacalcitol combined with UVB therapy was clinically not more effective than UVB monotherapy [11,13]. In combination with cyclosporine (CyA), tacalcitol once daily was more effective than three times weekly, but the 11% difference was not statistically significant [11,13]. It is recommended to not use vitamin D analogues prior to phototherapy because it may reduce the effectiveness of the both therapies.

### Harms

About a quarter of patients report mild discomfort (e.g., burning, pruritus, edema, peeling, dryness, erythema) at site of application, especially in the folds and on the face. Skin irritation is often transitory, may be less common for tacalcitol than for calcipotriol, and can be managed by reducing the dose and/or adding a TC. For the combination drug, the side-effect profile of TC applies. If used properly, the rate of adverse events is extremely low and is on the order of 0.01% [13]. Systemic adverse events such as hypercalcemia and parathyroid hormone suppression are very rare and are associated with an overdose [13]. Therefore, take total BSA that is treated into consideration (the maximum for the different vitamin analogues varies between 20 and 35%; see above) [11]. The rule of thumb is to use less than 100 g of calcipotriol per week [13]. Vitamin D analogues have not been shown to be teratogenic in mice, but should be avoided during pregnancy in humans. It is unclear whether this drug class is excreted in breast milk.

Altogether, there are no absolute contraindications for vitamin D analogues. Relative contraindications are patients with psoriasis pustulosa, disorders of calcium metabolism, those taking drugs affecting calcium metabolism (e.g., thiazide diuretics), severe renal or liver impairment, or during pregnancy and lactation [11,13].

### Comments

Of the vitamin D analogues, calcipotriol and calcitriol are equally modestly effective and superior to tacalcitol. Calcipotriol has been more extensively studied in mono and combination therapy. Combination with topical steroids in a combination drug is significantly superior to calcipotriol monotherapy. Vitamin D analogues may be irritative, but are safe in the long term if the dose remains within limits (e.g.,  $<30\%$  BSA or 100 g weekly for calcipotriol) and is not administered to patients with disorders affecting the calcium metabolism.

## Phototherapy

### How effective are different phototherapies for chronic plaque-type psoriasis?

#### Sources of information

### Ultraviolet B phototherapy

Besides broadband UVB (BB-UVB) phototherapy (280–315 nm), since the 1980s narrowband UVB (NB-UVB) phototherapy (wavelength around 311 nm) has also been used for treatment of psoriasis. “Selective UV therapy (SUP)” is irradiation with UVB rays with wavelengths between 300 and 320 nm in a unit with rotating base and fitted lamps. Excimer lasers have been used which emit monochromatic UVB light (308 nm).

Often, UVB therapy is combined with topicals, sometimes with systemics [14].

### Benefit

There is a big variation between the studies with UVB in relation to UV dose, number of exposures per week, and treatment duration. Often, time till clearance is mentioned as outcome parameter [11].

**Global estimate of efficacy** Based on RCT evidence, it is shown that with NB- and BB-UVB therapy 50–75% of patients achieve at least a 75 % improvement in PASI score after 4–6 weeks. The number of weeks needed to achieve this level of improvement decreases with the increasing number of exposures per week. There is limited RCT evidence that thrice-weekly UVB cleared psoriasis faster than twice-weekly UVB did. Clearance within 20 weeks was reported in 51%, 63%, and 75% of patients treated twice weekly with NB-UVB. Onset of action starts at 1–2 weeks [11].

Based on a comparison of RCTs of BB-UVB and NB-UVB, there was no statistically significant difference between thrice-weekly selective BB-UVB and thrice-weekly NB-UVB for clearance at the end of treatment, remaining clear at 3 and 6 months post treatment and withdrawal due to toxicity [10].

Excimer laser treatment is investigated in small non-RCTs for solitary psoriatic plaques. Partial remission to complete clearance of skin lesions was achieved in most to all treated patients after an 8-week treatment. A tapering schedule may help to maintain remission. Excimer treatment may be safe in children.

SUP treatment three times per week versus once daily showed a PASI 75 in 29% of patients versus 86% within 4 weeks in this group. One study comparing SUP with BB-UVB showed that SUP was more effective.

**Home ultraviolet B** Patients with psoriasis who are compliant, motivated, and adherent with instructions and follow-up examinations could, under dermatologist supervision, be considered appropriate candidates for home UVB therapy. A recent multicenter,

single-blind, randomized clinical trial of 196 patients from the Netherlands demonstrated that home NB-UVB is just as effective as outpatient-administered NB-UVB. In this study, 70% of patients treated at home compared with 73% treated in the outpatient setting reached PASI 50 [15].

**Ultraviolet B versus psoralen–ultraviolet A** Based on a comparison of RCTs of two- or three-times-weekly oral psoralen–UVA (PUVA) versus two- or three-times-weekly NB-UVB, statistically significantly better results were shown for PUVA in terms of relapse rate for clearers after 6–12 months and mean time to clearance after a maximum follow-up of 3 months.

In terms of PASI 75 at 3–4 months or after a maximum of 20 treatments, there was no statistically significant difference between two- or three-times-weekly NB-UVB and two- or three-times-weekly PUVA [10].

### Ultraviolet B in combination therapy

**Ultraviolet B with emollients** Emollients may increase the transmission of UV radiation by altering the optical properties of psoriatic skin lesions and improving therapeutic efficacy. Emollients such as mineral oil may be applied before UV exposure [16]. There are no RCTs to prove the benefit of concomitant use of emollients with UVB.

**Balneo phototherapy** There seems to be an additive benefit of combining a mineral salt water bath with phototherapy. UVB therapy preceded by mineral salt water bath or high-concentration mineral salt water bath may increase the PASI 75 response. UVB therapy alone led to a PASI 75 response in 50% (or 54%) of patients, and among those who were given a mineral salt water bath (or high-concentration mineral salt water bath) the rates were 73% (or 83%) after 6 weeks of treatment [11].

**Ultraviolet B with vitamin D derivatives** There are conflicting data of the beneficial effect of the combination of vitamin D derivatives plus UVB. Some studies show no superiority above UVB therapy alone [11]. However, RCTs suggest that combining NB-UVB with calcipotriol has a UVB-sparing effect [16].

If applied in combination with UVB therapy, vitamin D derivatives should be applied after UV exposure because some vitamin D analogues may be degraded after exposure to UV radiation. This combination therapy may be potential carcinogenic.

**Ultraviolet B with topical steroids** Response rates of UVB phototherapy in combination with steroids were similar to UVB monotherapy [11]. A synergistic effect is not seen. However, a more rapid clearing of psoriasis occurred when UVB was used in conjunction with topical fluocinolone or clobetasol propionate (used in combination with UVB and topical anthralin). Combined treatment of UV and topical steroids may result in a higher relapse rate. Thus, it is unclear whether the use of topical steroids in combination with UVB is beneficial [16].

**Ultraviolet B with tazarotene** UVB phototherapy may also be combined with tazarotene. In one study, the patients with combination treatment achieved at least 75% improvement in 82% of treated patients after 81 days, compared with 68% in the UVB monotherapy group [11]. The UV dose may need to be adjusted because of higher rates of burning.

**Ultraviolet B with dithranol** One study on the combination of three or five doses of dithranol and broadband UVB phototherapy showed comparable response rates of 40% and 44% (minimum 75% improvement of skin lesion after 8 weeks) for five-times-weekly therapy [11].

The Ingram scheme combines a tar bath, UVB phototherapy and dithranol. One study reported complete clearance of skin lesions in 82% of patients within 20 days.

**Ultraviolet B with coal tar (Goeckerman)** Methodological poor-quality studies are available for the combination of phototherapy and coal tar. Coal tar followed by UVB therapy has been studied in six small studies with various designs (UVB frequency, duration of contact, bilateral comparisons) and most frequently including hospitalized patients. This combination therapy seemed effective, but it ranged from 41% to 100% and was not always statistically superior to placebo ointment [11].

Although Goeckerman and Ingram regimens may be highly effective in clearing psoriasis, these combinations are far less popular in recent years. The treatments are time consuming and messy, and reimbursements for inpatient dermatologic care for psoriasis have been changed [16].

**Ultraviolet B with methotrexate** The combination of methotrexate (MTX) with UVB therapy may be beneficial with the promise of a reduction in dose-related toxicity [16]. There are preliminary indications that MTX could mediate increased phototoxicity of UVB radiation [11].

**Ultraviolet B with cyclosporine** The combination of CyA and UVB has not been studied extensively because of the increased risk of nonmelanoma skin cancer; there are no studies documenting the longer term safety of the combination and it should be avoided [16].

**Ultraviolet B with retinoids** Retinoids combined with UVB have been extensively studied and accelerate the response to phototherapy, reducing the cumulative dosage of UVB and the dose of acitretin required to achieve psoriasis clearance [16].

In an RCT comparing the combination of acitretin with NB-UVB versus acitretin and PUVA therapy, clearance was observed in 57% of patients in the former group compared with 63% in the latter [16].

When phototherapy is combined with acitretin, acitretin should be started approximately 2 weeks before the initiation of phototherapy, the standard dose being 25 mg/day for patients weighing 70 kg or more or 10 mg/day for those weighing less. The dosage and scheduling of BB-UVB or NB-UVB are managed according to the patient's skin type with appropriate reductions (approximately 25%) in the initial dosages of UV radiation. Acitretin has also been used in combination with home NB-UVB phototherapy. Acitretin in combination with UV therapy, despite the reduction of cumulative dosing, costs, and potential systemic toxicities, remains less used than expected given the potential benefits.

**Ultraviolet B with biologics** Only case reports are available to evaluate the effect of combining UVB phototherapy and biologic agents [16]. More research is needed.

## Harms

**Ultraviolet B (broad spectrum, 311 nm; selective ultraviolet therapy, 308 nm)** In general, limited data are available about undesirable

adverse effects of UVB therapy. Erythema is mentioned as a side effect of all UVB modalities, except for excimer laser (308 nm). The frequency of occurrence is unclear. The rate varies between 33% for BB-UVB twice weekly, 73% for NB-UVB and 65% for SUP. Symptoms related to severe dermatitis solaris are more common with excimer laser therapy. Other side effects are blistering, a burning sensation during therapy, as well as areas of brown discoloration and hyperpigmentation [11].

In general, the combination of topical therapies with phototherapy does not increase the rate of adverse effects.

Long-term use of UVB phototherapy results in sun damage and premature aging of the skin. Controversy exists about the potential carcinogenic effects of UVB phototherapy. Animal experiments have demonstrated the carcinogenic effects of UVB phototherapy. These appear to be less pronounced, however, in narrow-spectrum therapy than in broad-spectrum UVB [17]. In a systematic review (search date 2002) limited evidence was found that UVB treatment increases the risk of skin cancer during a follow-up period of around 25 years [18].

The combination of tar and UVB seems not to increase the incidence of nonmelanoma skin cancers over UVB alone [16].

## Comments

UVB is recommended for induction therapy for moderate to severe chronic plaque-type psoriasis in patients that cannot be controlled with topical treatments alone or if there are contraindications for topical therapy or involvement of a large BSA. Treatment with UVB phototherapy can be given two or three times a week [11].

Because of the lower risk of nonmelanoma skin cancer and owing to a better feasibility, UVB is preferred above PUVA, despite the superior efficacy of PUVA compared with UVB therapy alone.

The use of an excimer laser may be recommended for targeted therapy of individual psoriatic plaques.

Given the number of variables involved, there is a wide array of treatment protocols.

Consider topical adjunctive therapy in UVB patients who have recalcitrant plaques to phototherapy alone, or at difficult-to-treat or high-need sites [10]. The customary combination with many topicals may be recommended based on clinical experience, but not on the basis of the available data [11].

The NICE guidelines suggest [10]:

Offer other second- or third-line treatment options when: narrowband UVB phototherapy results in an inadequate response or is poorly tolerated or there is a rapid relapse following completion of treatment (rapid relapse is defined as greater than 50% of baseline disease severity within 3 months) or accessing treatment is difficult for logistical reasons (for example, travel, distance, time off work or immobility) or the person is at especially high risk of skin cancer.

UVB phototherapy is generally considered to be safe during pregnancy (low-quality studies) [17]. UVB phototherapy should not routinely be used as maintenance therapy.

Only trained personnel should give phototherapy. They should be competent in its use, and promote adherence to the indications for and contraindications to treatment, dosimetry, and national policy on safety standards for phototherapy [10].

Patients with a known history of lupus erythematosus or xeroderma pigmentosum should not be treated with phototherapy or photochemotherapy. Patients with a history of a photosensitivity disorder, taking photosensitizing medications, with a history of (familial) melanoma, with atypical nevi, with multiple risk factors

for melanoma, with multiple nonmelanoma skin cancers, or who are immunosuppressed as a result of organ transplantation should be screened carefully before initiating phototherapy or photochemotherapy [16].

Protective goggles should cover the eyes during UV light therapy. Unless psoriasis lesions are present and require UVB therapy, face, neck, backs of the hands, and genital regions should be protected from exposure to UV light.

The entire skin should be inspected for signs of cancerous lesions, precancerous lesions, and dysplastic nevus cell nevi before starting UV treatment. The patient should be informed about the course of therapy, possible side effects, and potential long-term risks – in particular, the increased risk of cancer as a result of therapy. Additional sun exposure should be avoided owing to its synergistic effect. Document the cumulative UV dose, number of UV exposures, and UV sessions [11]. Complete lists of contraindications are described in above-mentioned guidelines.

### Photochemotherapy (psoralen–ultraviolet A)

#### Benefit

Since the 1970s, the administration of photosensitizing psoralens followed by whole-body or partial-body UVA phototherapy (315–400 nm) has been supported by scientific findings. Psoralens may be given systemically, as oral PUVA therapy, or topically as a bath or cream [11].

There is a big variation between studies with PUVA in relation to UV dose, number of exposures per week, and treatment duration. Often, time till clearance is mentioned as an outcome parameter [11].

#### Global estimate of efficacy

**Oral psoralen–ultraviolet A therapy** Most studies used 8-methoxypsoralen 0.6 mg per kilogram of body weight as the photosensitizer. 5-Methoxypsoralen 1.2 mg per kilogram of body weight is also possible but much less investigated. In one comparative study, 8-methoxypsoralen was found to be the superior photosensitizer. The treatment frequency was two to four exposures per week. Based on skin type or minimum phototoxic dosage, the UV dosage was increased.

In the majority of studies, more than 75–100% of patients achieved a score of 75% improvement, even at only two exposures per week. Two studies directly compared increasing the dosage based on skin type versus an MPD-based dosage increase with variable results. Many patients experience remission up to 6 months.

**Bath psoralen–ultraviolet A** There are studies examining the efficacy of bath PUVA, administered in two, three, or four sessions per week. Studies comparing bath PUVA with oral PUVA therapy with a same number of treatments showed equal efficacy. In one study, 64% of patients reported at least a 75% improvement in skin lesions; another showed complete clearance in all patients, which occurred within 10 weeks for twice-weekly therapy or within 4 weeks for four-times-weekly treatment [11].

**Cream psoralen–ultraviolet A** In a study comparing cream (three times per week) with oral PUVA, four-times-weekly use of cream PUVA therapy led to complete clearance in 88% of treated patients, which was lower than in the oral PUVA group [11].

Three studies compared cream PUVA with UVB 311 nm. In one study the effectiveness was the same as with 311 nm therapy [11].

**Psoralen–ultraviolet B** Two studies compared the efficacy of psoralen and UVB with classic oral PUVA therapy. In 6–12 weeks, oral PUVA was shown to be superior (complete clearance in 86% or 84% of oral PUVA patients compared with 77% or 63% of PUVB) [11]. A systematic review included five studies in which no difference was shown [18].

#### Combination therapy

**Psoralen–ultraviolet A with ultraviolet B** Small studies suggest that the combination of PUVA and BB-UVB, NB-UVB, or excimer laser may lead to improved results within shorter periods of time [16]. In one study, the combination of oral PUVA and UVB phototherapy led to complete clearance in all patients within 15–18 sessions. Combined treatment was superior to oral PUVA monotherapy in the comparison group (clearance in 73% of patients within 20 treatments) [11].

The quality of studies with accompanying treatments such as balneotherapy, bath therapy, or climatotherapy is limited [11].

**Psoralen–ultraviolet A with vitamin D3 derivatives** The combination of topical calcipotriol cream or ointment with PUVA leads to a decrease in the duration of PUVA therapy along with an improved clinical response [16]. The combination of calcipotriol with oral PUVA therapy increases its effectiveness (PASI 75 of 87% of combined treated patients in 22 days vs 63% after 34 days in the PUVA group) [11]. For combination use of vitamin D derivatives with PUVA, up to one-fourth of patients experience adverse effects, usually erythema [11].

**Psoralen–ultraviolet A with tazarotene** The combination of PUVA and tazarotene has been anecdotally reported to be synergistic [16].

**Psoralen–ultraviolet A with topical steroids** The combination of betamethasone with oral PUVA may have a synergistic effect. The duration till clearance in the combined group is shorter (average of 13.6 days) compared with oral PUVA (average 20.25 days) [11]. However, it is not clear whether topical steroids combined with oral PUVA is a useful combination: one study found that the combination led to faster clearing without any shortening in the duration of remission, whereas another study found that adding topical steroids results in shorter remissions [16].

**Phototherapy with dithranol** The Ingram scheme combines a tar bath, UV phototherapy, and dithranol. The only study that was included in the guidelines on this treatment method reported complete clearance of skin lesions in 82% of patients within 20 days; in the comparison group, which was given oral PUVA, this same was true for 91% within 34 days.

**PUVA with retinoids** Because of the increased risk for developing cutaneous malignancies with PUVA, PUVA may be administered in combination with other medications such as retinoids or in rotation with other therapies to minimize the total dosage of PUVA [16]. The combination of oral retinoids with PUVA is more effective than monotherapy with either acitretin or PUVA alone. When adding an oral retinoid to a regimen of PUVA therapy, both the number of PUVA treatments and the total amount of UVA exposure are decreased.

In fact, acitretin, when combined with PUVA therapy, is associated with a decreased incidence of squamous cell carcinoma (SCC).

The optimal approach to combination therapy is to initiate treatment with an oral retinoid for approximately 2 weeks before adding PUVA treatment.

Because of their teratogenicity, oral retinoids are contraindicated in women of childbearing potential [16].

*Psoralen-ultraviolet A with cyclosporine* PUVA treatment has an increased risk for developing SCC when subsequently treated with CyA; this combination should be avoided [16].

*Psoralen-ultraviolet A with methotrexate* Although some studies suggest that the combination of PUVA and MTX is more effective than either therapy alone, the safety of this combination has been questioned [14]. The side effects are not yet defined and require long-term study. One potential side effect of combined MTX-PUVA therapy is increased phototoxicity [11].

*Psoralen-ultraviolet A with biologics* No studies evaluating the safety and efficacy of the combination of any biologic agents with PUVA are available [16].

*Narrowband ultraviolet B compared with oral psoralen-ultraviolet A* Based on a comparison of RCTs of two- or three-times-weekly oral PUVA versus two- or three-times-weekly NB-UVB showed statistically significantly better results for PUVA in terms of relapse rate for clearers after 6–12 months and mean time to clearance after a maximum follow-up of 3 months.

In terms of PASI 75 at 3–4 months or after a maximum of 20 treatments, there was no statistically significant difference between two- or three-times weekly NB-UVB and two- or three-times weekly PUVA [10].

One study demonstrated similar rates of clearing with both treatments twice weekly. A double-blind RCT compared NB-UVB with PUVA in 93 patients and demonstrated more patients with complete remission with longer remission times in fewer treatment sessions with oral PUVA [16].

### Harms

In general, limited data are available about undesirable short-term adverse effects of PUVA therapy. Side effects of oral PUVA are erythema, pruritus, and nausea. Most studies report erythema in about 50% (9–80%) of patients. Most other studies reported pruritus in 25–46% (in one study in about 83%). Nausea is the third most commonly reported side effect, affecting around 35% of patients. Dizziness is often reported as a relevant adverse effect, but only one study gave an exact figure of 60% [16].

With bath PUVA, erythema and pruritus are the most common side effects of therapy. Compared with oral PUVA given at the same frequency, the results for these two side effects favor bath PUVA. Nausea did not occur at all. Insufficient data are available on the carcinogenic risk of long-term topical PUVA [11].

Erythema is a rare side effect of cream PUVA (5%). Blistering is also reported [16].

In general, the combination of topical therapies with phototherapy does not increase the rate of adverse effects [16].

### Long-term safety of psoralen-ultraviolet A

The carcinogenic effects of oral PUVA are undisputed. There is an association with an increased risk of developing spinocellular and basal cell cancer, which increases depending on cumulative UVA dose. Although there are reports on an increased risk of melanoma

following long-term therapy, the actual risk is still unclear. In two cohort studies, after a mean follow-up of 14.7 years no increase in the risk of spinocellular carcinoma was found. This suggests that bath PUVA is possibly safer than oral PUVA [18].

Oral PUVA therapy can also lead to disorders of pigmentation, brown spots (PUVA lentigines), and cataracts [17].

### Comments

PUVA is recommended for induction therapy for moderate to severe chronic plaque-type psoriasis, especially if there is involvement of a large BSA. However, NB-UVB therapy may be considered as the first choice for phototherapy. Feasibility is better and there is a lower risk of malignancy. PUVA may be offered to people with plaque psoriasis that cannot be controlled with topical alone or UVB treatments. Treatment with PUVA can be given two or three times a week.

Given the number of variables involved, there is a wide array of treatment protocols [11].

The NICE guidelines mention [10]:

Offer other second- or third-line treatment options when: PUVA results in an inadequate response or is poorly tolerated or there is a rapid relapse following completion of treatment (rapid relapse is defined as greater than 50% of baseline disease severity within 3 months) or accessing treatment is difficult for logistical reasons (for example, travel, distance, time off work or immobility) or the person is at especially high risk of skin cancer.

Consider topical adjunctive therapy in PUVA patients who have recalcitrant plaques to phototherapy alone, or at difficult-to-treat or high-need sites [10]. The customary combination with many topicals may be recommended based on clinical experience, but not on the basis of the available data [11].

Only trained personnel should give phototherapy. They should be competent in its use, and promote adherence to the indications for and contraindications to treatment, dosimetry, and national policy on safety standards for phototherapy [10]. Patients need to be clinically monitored during treatment. Special attention should be paid to the therapeutically desirable level of erythema [11].

Patients with a known history of lupus erythematosus or xeroderma pigmentosum should not be treated with phototherapy or photochemotherapy. Patients with a history of a photosensitivity disorder, taking photosensitizing medications, with a history of (familial) melanoma, with atypical nevi, with multiple risk factors for melanoma, with multiple nonmelanoma skin cancers, or who are immunosuppressed as a result of organ transplantation should be screened carefully before initiating phototherapy or photochemotherapy [16].

Protective goggles should cover the eyes during UV light therapy. Unless psoriasis lesions are present and require PUVA therapy, face, neck, backs of the hands, and genital regions should be protected from exposure to UV light.

The entire skin should be inspected for signs of cancerous lesions, precancerous lesions, and dysplastic nevus cell nevi before starting UV treatment. The patient should be informed about the course of therapy, possible side effects, and potential long-term risks – in particular, the increased risk of cancer as a result of therapy. Additional sun exposure should be avoided owing to its synergistic effect. Document the cumulative UV dose, number of UV exposures, and UV sessions [11].

Ensure that all phototherapy equipment is safety checked and maintained in line with local and national policy [10].

PUVA should not be applied to pregnant and nursing patients and avoided in patients with lighter skin types (Fitzpatrick type I and II), in patients with a personal history of skin cancer, or in people who have already received 150 PUVA treatments or more, and patients who are likely to require CyA or long-term MTX.

Insufficient evidence is available for treating pediatric psoriasis [17]. Do not routinely use PUVA as maintenance therapy. Do not routinely offer co-therapy with acitretin when administering PUVA [10].

Do not use PUVA for pregnant or nursing women. PUVA treatment should be avoided in children, in patients with lighter skin types (Fitzpatrick type I and II), in patients with a personal history of skin cancer, or in people who have already received 150 PUVA treatments or more, patients who are likely to require CyA or long-term MTX.

When considering PUVA for psoriasis, the patient should be informed about the course of therapy, possible side effects, and potential long-term risks – in particular, the increased risk of cancer as a result of therapy. Additional sun exposure should be avoided owing to its possibly synergistic harm. Document the cumulative UV dose, number of UV exposures, and UV sessions [11]. Offer lifetime skin cancer surveillance to people treated with PUVA who have had more than 150–200 PUVA treatments (1000 J/cm<sup>2</sup>) or developed skin cancer [16,17]. Complete lists of contraindications are described in the above-mentioned guidelines.

## Systemic treatment of chronic plaque-type psoriasis

### How effective are systemic treatments for limited stable chronic plaque psoriasis?

#### Acitretin

##### Sources of information

- NICE National Clinical Guideline Centre. Psoriasis, Management of Psoriasis, Clinical Guideline, October 2012 (search date March 8, 2012, Medline, Embase, Cochrane, CINAHL) [10];
- S3 – Guidelines for the treatment of psoriasis vulgaris: update 2011 (search date November 2009, Medline, Embase, Cochrane) [11].

##### Benefit

**Global estimate of efficacy** With acitretin in a dosage of 40 mg/day a PASI 75 response can be expected in about 23–30% of the patients [11]. The results reported in the trials show a large heterogeneity.

**Acitretin versus placebo** In three trials comparing acitretin versus placebo, varying results were seen with respect to the statistical superiority of its efficacy when compared with placebo [10]. A dose of 50 mg acitretin was significantly better than placebo at week 8 [10], whereas lower dosages (10 and 25 mg) failed to achieve statistical superiority at week 8. In another trial, statistical superiority was not even achieved with a dosage of 75 mg [10].

**Different dosages of acitretin** One study comparing acitretin 50 or 75 mg with 10 mg acitretin showed better improvement with the high dosages with respect to scaling, erythema, thickness, and pustulation at 8 weeks [10]. Another small trial showed better response rates with acitretin 50–75 mg than with acitretin 10–25 mg [11].

**Acitretin versus etanercept** Two trials compared acitretin 0.4 mg per kilogram body weight versus etanercept twice weekly 50 mg and

twice weekly 25 mg. In both trials, response rates were better for etanercept than for acitretin [11].

**Acitretin in combination with etanercept** One trial looked at a treatment with etanercept 25 mg twice weekly versus acitretin 0.4 mg per kilogram body weight daily versus the combination of once-weekly etanercept 25 mg with acitretin 0.4 mg per kilogram body weight daily. After 24 weeks, both etanercept groups showed statistically significant better results than acitretin alone [11].

**Acitretin in combination with ultraviolet therapy** See section on phototherapy.

##### Harms

Most people experience mucocutaneous adverse effects, such as dry skin, cheilitis, and conjunctivitis. Mucocutaneous effects are generally mild. Increased serum cholesterol and triglyceride concentrations occurred in about half of the people. Occasionally, acute hepatitis occurred, possibly as an idiosyncratic hypersensitivity reaction. Radiographic evidence of extraspinal tendon and ligament calcifications has been documented. In a small number of patients, acitretin is transformed into etretinate. This is additionally promoted by alcohol consumption. Etretinate accumulates in the body fat and can cause a long-term safety risk, especially in women of childbearing age.

##### Comments

The efficacy of acitretin as a monotherapy in low dosages is rather small; the use of higher dosages is usually accompanied by an increase in adverse drug reactions. Giving acitretin to women of childbearing age should be avoided. If it is given to women of childbearing age, effective contraception must be given for 1 month before starting acitretin, throughout the treatment, and for 2 years after stopping acitretin treatment. Acitretin may be considered for special cases such as patients with HIV or a prior history of malignancies.

##### Fumaric acid esters

The preparation contains a mixture of dimethyl fumarate and three salts of ethyl hydrogen fumarate. Dimethyl fumarate is considered to be the actual active ingredient. Fumaric acid derivatives are widely used in Germany but are not licensed in other European countries or in the USA.

##### Sources of information

- S3 – Guidelines for the treatment of psoriasis vulgaris: update 2011 (search date November 2009, Medline, Embase, Cochrane) [11];
- Griffiths *et al.*: A systematic review of treatments for severe psoriasis [19].

##### Benefit

**Global estimate of efficacy** With fumaric acid derivatives a PASI 75 response can be expected in about 50–70% of the patients after 16 weeks [11].

**Fumaric acid esters versus placebo** Two of the RCTs (123 people) compared a mixture of dimethylfumaric and monoethylfumaric acid esters versus placebo. Pooled analysis found that this mixture of fumaric acid derivatives reduced severity significantly more than placebo at 16 weeks. The remaining RCTs published in a single

paper documented that the response to dimethylfumaric acid ester was significantly greater than placebo at 16 weeks, whereas the response to monoethylfumaric acid ester was no greater than to placebo [19].

### Harms

All of the RCTs had high withdrawal rates. Acute adverse effects, including flushing and gastrointestinal symptoms, were reported in up to 75% of the patients. Additional adverse effects include diarrhea, stomach cramps, flushing, and lymphocytopenia [19].

### Comments

Fumaric acid esters show better efficacy than placebo. The clinical experience in some countries with fumaric acid esters, in particular in Germany, is much greater than the documentation of efficacy and safety of their use in clinical studies. In Germany, they are widely used for long-term therapy and are considered a very safe treatment. Clinical use of the drug is limited by gastrointestinal effects and flushing.

### Methotrexate

#### Sources of information

- NICE National Clinical Guideline Centre. Psoriasis, Management of Psoriasis, Clinical Guideline, October 2012 (search date March 8, 2012, Medline, Embase, Cochrane, CINAHL) [10];
- S3 – Guidelines for the treatment of psoriasis vulgaris: update 2011 (search date November 2009, Medline, Embase, Cochrane) [11].

### Benefit

**Global estimate of efficacy** With MTX a PASI 75 response can be expected in about 25–50% of the patients [11].

**Methotrexate versus placebo** Two trials compare MTX versus placebo. MTX was statistically better than placebo for PASI 50 and PASI 75 at 4–6 months [10].

**Methotrexate versus cyclosporine** Four trials compared CyA with MTX. The studies identified do not show a clear superiority of one over the other. For some study outcomes CyA was better than MTX (e.g., PASI 75 after 12 weeks), for others MTX was better than CyA (e.g., final PASI at week 12) [10]. The time till the onset of action is faster with CyA than with MTX [10].

### Harms

The most common symptomatic adverse effect of MTX therapy is nausea, which may affect up to one-third of treated patients. Its most important potential side effect is acute myelosuppression, which is the cause of most of the rare deaths attributable to it when used as a therapy for psoriasis [20]. MTX is eliminated largely via the kidneys, and toxic levels may build up rapidly in the presence of renal impairment. Particular care is required in the elderly, in whom renal function may deteriorate rapidly in response to acute illness; dietary folate deficiency may add to the toxicity. Some studies have shown that circulating homocysteine levels are elevated in psoriasis patients receiving MTX, but that folate supplementation can reverse this abnormality; since raised homocysteine levels have been associated with atherothrombotic vascular disease, it may therefore be advisable for all patients on MTX to receive folate supplementation [21]. Certain drugs, particularly nonsteroidal anti-inflammatory agents, aspirin, trimethoprim, and sulfona-

mides, may interfere with MTX pharmacokinetics and thus increase the risk of toxicity, particularly in the presence of impaired renal function. Long-term MTX treatment carries with it a risk of hepatic fibrosis and cirrhosis, which is considered to increase with cumulative dose. In general, patients with diabetes, obesity, and relevant alcohol consumption are considered to be at a higher risk of hepatotoxicity. However, and probably mostly due to too small and not well-designed studies, it has not been possible to clearly define possible risk groups or the relevance of a cumulative dose of more than 3 g in the respective studies [10].

Safety monitoring for MTX remains a challenge. Current guidelines suggest using standard liver function tests and serial serum procollagen III levels for monitoring [10,11]. Pulmonary disease associated with MTX has been described as an acute or chronic interstitial pneumonitis [22]. MTX appears to double the risk of developing SCC in patients exposed to psoralen plus UVA and may be an independent risk factor for this type of cancer in patients with psoriatic arthritis [23]. A higher risk of lymphoproliferative diseases in long-term users has been suggested by a few case reports. On the basis of data from a large case series (248 patients), the cumulative incidence of lymphoma is not expected to be much higher than 1% [24].

### Comments

In most countries MTX is the most frequently prescribed systemic treatment. It is considered to be particularly valuable for patients with concomitant arthritis. The clinical experience with MTX is much greater than the documentation of its efficacy and safety in clinical studies. Recently published trials have yielded lower efficacy data than earlier trials, and the data must be interpreted with caution; different initial dosages may influence early study assessments. For some patients it seems to be a very suitable and safe long-term treatment. Patients using MTX should be closely monitored for liver toxicity and should be advised to limit their alcohol consumption.

### Cyclosporine

#### Sources of information

- NICE National Clinical Guideline Centre. Psoriasis, Management of Psoriasis, Clinical Guideline, October 2012 (search date March 8, 2012, Medline, Embase, Cochrane, CINAHL) [10];
- S3 – Guidelines for the treatment of psoriasis vulgaris: update 2011 (search date November 2009, Medline, Embase, Cochrane) [11];
- Griffiths *et al.*: A systematic review of treatments for severe psoriasis [19].

### Benefit

**Global estimate of efficacy** With CyA a PASI 75 response can be expected in about 50–75% of the patients after 12–16 weeks [11].

**Cyclosporine versus placebo for clearance** Four RCTs compare CyA versus placebo. In most trials, CyA was significantly better than placebo [25–28].

**Cyclosporine versus placebo for maintenance** Five RCTs looked at a treatment with CyA to maintain remission. Two RCTs compared two doses of CyA (1.5 mg/kg or 3.0 mg/kg daily) versus placebo. Both RCTs found that 3.0 mg/kg daily CyA was better than placebo for maintaining remission. The third RCT compared two different CyA formulations and found no significant difference in the

response after 24 weeks between an oil-based and microemulsion preconcentrate formulation. The fourth RCT (400 patients) found that tapering the CyA dose marginally increased the time to relapse in comparison with abrupt stopping of CyA (time to relapse 113 days with tapered CyA versus 109 days with abrupt stopping;  $P = 0.038$ ). The fifth RCT (37 patients) found that, over the 36 months of treatment, continuous CyA was more effective for maintaining remission than intermittent CyA (remission maintained for 69% of the observation period with continuous CyA versus 32% with intermittent treatment) [19].

*Cyclosporine versus methotrexate* See section on methotrexate.

### Harms

CyA can be associated with dose-related increases in hypertension and reduced renal function [19]. Observational evidence suggests that the incidence of these adverse events increases over time. In a case-series follow-up study of 122 consecutive patients treated continuously with CyA for 3–76 months at dosages not exceeding 5 mg/kg daily, 104 patients discontinued treatment [29]. The mean percentage of patients who discontinued treatment due to adverse effects (mostly renal dysfunction and hypertension) rose from 14% at 12 months to 41% at 48 months. One prospective cohort study documented an increased risk of malignancies in 152 people with psoriasis treated with CyA for up to 5 years. Malignancies were diagnosed in 3.8% of patients, with a standardized incidence ratio of 2.1 in comparison with the general population. There was a sixfold increase in the incidence of skin cancer in comparison with the general population, while non-skin malignancies did not show a significantly increased risk [30]. The additional use of UV, especially PUVA, strongly increases the risk of nonmelanoma skin cancer.

### Comments

CyA is an established short-term treatment option for moderate to severe psoriasis. Relapses are often seen on withdrawal, and long-term treatment is limited by adverse effects (mainly renal dysfunction and hypertension).

### Adalimumab

#### Sources of information

- NICE National Clinical Guideline Centre. Psoriasis, Management of Psoriasis, Clinical Guideline, October 2012 (search date March 8, 2012, Medline, Embase, Cochrane, CINAHL) [10];
- S3 – Guidelines for the treatment of psoriasis vulgaris: update 2011 (search date November 2009, Medline, Embase, Cochrane) [11], tables updated searching for “adalimumab” and “psoriasis” using RCT filter on Medline on September 15, 2012;
- Singh *et al.*: Adverse effects of biologics: a network meta-analysis and Cochrane overview [31].

### Benefit

*Global estimate of efficacy* With adalimumab a PASI 75 response ranging between 71 and 80% can be expected after 16 weeks [11].

*Adalimumab versus placebo* See Table 26.1 (modified and updated from [11]).

*Adalimumab for patients with or without prior exposure to biological therapy* Three studies assessed the likeliness of a treatment success if the patient has had prior exposure to biological therapy. In the

studies included, there was no statistically significant difference with respect to a PASI 75 response at week 16 or at week 24 if the patient had prior biologic treatment or not [10].

### Harms (based on German S3 guidelines [11])

Injection site reactions were the most commonly reported adverse effect. In placebo-controlled studies they were seen with adalimumab in 20% of the patients and in 14% of placebo-treated patients). Adalimumab therapy can be associated with an increased rate of infections, particularly infections of the upper respiratory passages, bronchitis, and infections of the urinary passages. Severe infections such as pneumonia, septic arthritis, post-operative infections, erysipelas, phlegmonous infections, diverticulitis, and pyelonephritis can also occur.

Less frequently observed adverse events include thrombocytopenia and leukopenia, exanthema, urticaria, angioedema, pruritus, respiratory distress, as well as tightness in the chest.

Induction of auto-antibodies (ANA, anti-dsDNA antibodies) and lupus-like syndrome has been reported in rare cases. A Cochrane review by Singh *et al.* from 2011 summarizes the safety data from several biologics, including adalimumab [31]. It is important to note that this analysis also includes other patient groups among psoriasis patients, such as those with rheumatoid arthritis and patients with Crohn's disease. With adalimumab compared with placebo there was neither a significant increase in the OR for the “total number of adverse events,” the “number of withdrawals due to adverse events,” nor in “serious infections or serious adverse events.”

### Comments

Adalimumab shows good efficacy in the treatment of psoriasis vulgaris. With a large number of patients having been treated with adalimumab also in other indications, the risk–benefit profile appears to be good.

### Etanercept

#### Sources of information

- S3 – Guidelines for the treatment of psoriasis vulgaris: update 2011 (search date November 2009, Medline, Embase, Cochrane) [11], tables updated searching for “etanercept” and “psoriasis” using RCT filter on Medline on September 15, 2012;
- Singh *et al.*: Adverse effects of biologics: a network meta-analysis and Cochrane overview [31].

### Benefit

*Global estimate of efficacy* With etanercept  $2 \times 25$  mg or  $1 \times 50$  mg weekly about 35% or 38% of patients achieve PASI 75 after 12 weeks. During a therapy with  $2 \times 50$  mg every week for 12 weeks, about 50% of patients achieve a PASI 75 response [11].

*Etanercept versus placebo* The study results of the major trials are provided in Table 26.2 (adapted from [11]).

### Harms (based on German S3 guidelines [11])

Placebo-controlled studies report injection site reactions in 14% of psoriasis patients treated with etanercept (11–17%) compared with 7% in the placebo group [32]. An elevated risk of serious infection or malignancies has to be considered, especially with respect to lymphoma. As with other tumor necrosis factor (TNF)-blockers, undesirable hematological effects, demyelinating diseases, and autoimmune processes may occur.

A Cochrane review by Singh *et al.* from 2011 summarizes the safety data from several biologics, including etanercept [31]. It is important to note that this analysis also includes other patient groups among psoriasis patients, such as those with rheumatoid arthritis and patients with Crohn's disease. With etanercept, when compared with placebo, there was neither a significant increase in the OR for the "total number of adverse events," the "number of withdrawals due to adverse events," nor in "serious infections or serious adverse events."

### Comments

Etanercept shows moderate efficacy in the treatment of plaque-type psoriasis during induction therapy. The dosage of once-weekly 50 mg or twice-weekly 50 mg should be preferred over twice-weekly 25 mg. With a large number of patients also having been treated with etanercept in other indications, the risk-benefit profile appears to be good.

## Infliximab

### Sources of information

- S3 – Guidelines for the treatment of psoriasis vulgaris: update 2011 (search date November 2009, Medline, Embase, Cochrane) [11], tables updated searching for "infliximab" and "psoriasis" using RCT filter on Medline on September 15, 2012;
- Singh *et al.*: Adverse effects of biologics: a network meta-analysis and Cochrane overview [31].

### Benefit

**Global estimate of efficacy** With infliximab, 75–88% of the patients achieve a PASI 75 response after 16 weeks [11].

**Infliximab versus placebo** The study results of the major trials are presented in Table 26.3 (adapted from [11]).

### Harms (based on German S3 guidelines [11])

The most commonly reported adverse effects of infliximab are infusion reactions. Usually these reactions are mild, but the probability of an infusion reaction is increased in patients with infliximab-specific antibodies and may include severe reactions such as anaphylactoid reactions. In addition, infliximab therapy has been associated with serious infections. The use of infliximab carries a risk of reactivation and generalization of preexisting latent tuberculosis or other preexisting infections. Infliximab has been associated with exacerbation of existing cardiac insufficiency.

Demyelinating diseases of the central nervous system have been observed, and multiple sclerosis may be exacerbated. Especially in patients with preexisting liver damage (e.g., hepatitis), hepatotoxicity has been observed. In psoriasis patients, elevated transaminase levels have been reported. Leukopenia, neutropenia, thrombopenia, pancytopenia, and related deaths have been reported in patients who have rheumatoid arthritis or Crohn's disease and were taking infliximab. The number of cases of lymphoma in patients treated with anti-TNF- $\alpha$  antibodies is reportedly minimally higher than in control groups. The risk of other malignancies is no greater than the risk reported for controls. It is unclear whether exposure to infliximab could increase the incidence of these diseases. Some patients who take infliximab develop antinuclear antibodies in serum and some also develop dsDNA-antibodies. The reversible onset of lupus erythematosus-like syndrome is occasionally reported.

A Cochrane review by Singh *et al.* from 2011 summarizes the safety data from several biologics, including infliximab [31]. It is important to note that this analysis also includes other patient groups among psoriasis patients, such as those with rheumatoid arthritis and patients with Crohn's disease. With infliximab, the OR for an increase in the "total number of adverse events" and "withdrawals due to adverse events" compared with placebo were significantly increased (OR, 1.55; 95% CI, 1.01–2.359; and OR, 2.34; 95% CI, 1.4–4.14). No statistical significant increase in "serious infections" or "serious adverse events" was seen for infliximab when compared with placebo.

### Comments

Infliximab shows the best efficacy and fastest onset of action in the treatment of psoriasis vulgaris during induction therapy. The very good efficacy has to be counterbalanced with the somewhat increased risk of side effects compared with the other TNF- $\alpha$  antagonists.

## Ustekinumab

### Sources of information

- S3 – Guidelines for the treatment of psoriasis vulgaris: update 2011 (search date November 2009, Medline, Embase, Cochrane) [11], tables updated searching for "ustekinumab" and "psoriasis" using RCT filter on Medline on September 15, 2012;
- Ryan *et al.*: Association between biologic therapies for chronic plaque psoriasis and cardiovascular events: a meta-analysis of randomized controlled trials [33];
- Tzellos *et al.*: Re-evaluation of the risk for major adverse cardiovascular events in patients treated with anti-IL-12/23 biological agents for chronic plaque psoriasis: a meta-analysis of randomized controlled trials [34].

### Benefit

**Global estimate of efficacy** With ustekinumab, 67% of the patients can be expected to achieve a PASI 75 response after 16 weeks [11].

**Ustekinumab versus placebo** The study results of the major trials are presented in Table 26.4 (adapted from [11]).

### Harms (based on German S3 guidelines [11])

Ustekinumab is the newest systemic antipsoriatic drug available and the available safety data are limited if compared with the other systemic treatments. In two major trials, PHOENIX-1 and PHOENIX-2, the rate of common and serious side effects related to ustekinumab was comparable to that of placebo. The most common side effects in the two trials were: infections (general), 21.5% and 31.4% (placebo, 20% and 26.7%); specifically nasopharyngitis, 6.8% and 10.2% (placebo, 7.1% and 8.6%); upper respiratory infections, 2.9% and 7.1% (placebo, 3.4% and 6.3%); headache, 4.6% and 5.5% (placebo, 2.4% and 4.1%); and arthralgia, 2.4% and 3.4% (placebo, 2.7% and 2.9%). The rates of serious adverse events in the two trials were 0.8% and 2.0%, and thus within the same ranges as in the placebo group (0.8% and 2.0%). The rate of severe infections was low (<1%) in subsequent phases of the study as well. In both studies together there were 15 malignancies, including 11 cases of skin cancer, during the total observation period. There is ongoing discussion regarding possible major adverse cardiovascular events with the use of ustekinumab. Depending on the statistical approaches taken, meta-analyses of published data came to differing conclusion regarding this association. More data are necessary

for a final assessment, and special attention has to be given to cardiovascular risk factors before initiating and during a treatment with ustekinumab.

### Comments

Ustekinumab shows good efficacy and a fast onset of action in the treatment of psoriasis vulgaris during induction therapy. Since ustekinumab has been used for a limited number of patients, special attention has to be paid to safety aspects.

### Alefacept

Alefacept is a recombinant protein that binds to the CD2 receptor on memory effector T lymphocytes. With alefacept, a PASI 75 response can be expected in about 21% of the patients [11]. Alefacept is approved for the treatment of psoriasis in the USA and Switzerland only, and its distribution has currently been ceased.

## How effective are treatments for guttate psoriasis?

### Sources of information

- Chalmers *et al.*: Interventions for guttate psoriasis [35];
- Owen *et al.*: Antistreptococcal interventions for guttate and chronic plaque psoriasis [36].

Both reviews were updated using the same search terms in the databases Medline, Embase, and Cochrane (search data August 16, 2012).

## Antistreptococcal interventions

### Benefits

**Antibiotic therapy** The Cochrane review included only one RCT examining the use of antistreptococcal interventions and found no evidence of benefit in any patient receiving either of two antibiotic regimens [36]. Our literature update identified two additional trials investigating the usefulness of antistreptococcal interventions. In one trial, antipsoriatic treatment in both groups was done using betamethasone dipropionate 0.05% cream and UVB. The additional benefit of adding penicillin in one group was assessed and no relevant difference could be seen [37]. The study has to be considered largely underpowered to detect any difference. Another trial randomized 43 psoriasis patients to a treatment with erythromycin, with phenoxymethylpenicillin, or no treatment. Additional antipsoriatic treatments were not applied. No statistically significant improvements were seen in any group [38].

**Tonsillectomy** One trial examining the effects of tonsillectomy on the recurrence or persistence of guttate psoriasis was found. Twenty-nine patients with chronic psoriasis and history of exacerbation after sore throat were randomly assigned to tonsillectomy ( $n = 15$ ) or control ( $n = 14$ ) groups and monitored for 2 years. The mean PASI score decreased significantly in the treatment group, both with time after tonsillectomy and compared with the controls. Eighty-six percent of the controls used topical treatment at some time point during the study, compared with only 27% in the treatment group. Methodological limitations apply since, after tonsillectomy treatments, regimens were not clearly defined. Antipsoriatic treatments were given as considered necessary by the physicians and/or patients and there was no individual reporting on the antipsoriatic treatments given (change in PASI with respect to treatment given) [39].

### Harms

There is insufficient information. Tonsillectomy carries with it a risk of a serious adverse outcome, especially post-operative bleeding.

### Comments

There is no available evidence that the use of antibiotics improves guttate psoriasis. Larger trials with a longer follow-up may be necessary to yield relevant findings. There are indications that patients with chronic psoriasis and a history of exacerbation after sore throat may benefit from tonsillectomy.

## How effective are systemic treatments for acropustulosis (acrodermatitis continua of Hallopeau)?

An additional de novo search was run for the term “acrodermatitis continua of Hallopeau” using Medline (search date August 16, 2011).

We found no RCTs on treatments for acrodermatitis continua of Hallopeau. Only case reports were identified. Several case reports claim good efficacy of adalimumab, etanercept, and infliximab on acrodermatitis continua of Hallopeau. Publications on the success of topical treatments are also available and report on the efficacy of betamethasone, calcipotriol, and tacrolimus, usually applied as combination therapy. Some case reports claim efficacy also for “targeted” UVB therapy or topical 8-methoxypsoralen with UVB. Case reports published before the era of the biologics also report successful treatments with CyA, acitretin, MTX, and dapsone, which are likely to be still used with success, but with a loss of interest in these drugs these are not reported as case reports anymore.

### Key points

The main limitation of the available evidence is the lack of trials comparing different therapeutic options.

### Chronic plaque psoriasis

- There is sufficient evidence to show the efficacy of MTX, CyA, fumaric acid esters, adalimumab, etanercept, infliximab, and ustekinumab. The data on the efficacy of acitretin is limited and varies with respect to the dosage.
- There is good evidence of a risk of serious harm from the major treatment modalities used for treating severe psoriasis, including skin cancer with PUVA and heliotherapy, hypertension and renal impairment with CyA, myelosuppression and hepatic fibrosis with MTX, and teratogenicity with systemic retinoids.
- The safety data for the biologic treatments is increasing but has still to be interpreted with caution, especially with respect the newest treatment ustekinumab.

### Guttate psoriasis

- There is virtually no guidance from controlled trials on how to manage guttate psoriasis.

## Background

### Definition

Lichen planus (LP) is a chronic inflammatory disease affecting mainly the oral mucosa and the skin. Cutaneous LP is typically a pruritic eruption of shiny, violaceous, flat, polygonal papules, mainly localized on the front of the wrists, the lumbar region, and around the ankles. The most frequent oral presentation is asymptomatic reticular LP, but painful erosive or ulcerative areas may appear. LP may also involve the genitals, esophagus, conjunctiva, nails, and scalp [1].

### Prevalence

The prevalence in the general population of cutaneous LP is 0.1% among women and 0.3% among men, and the prevalence of oral LP is 2.3% among women and 1.5% among men [2,3]. The oral mucosa is the most frequently affected site [1].

### Etiology

The pathogenesis of LP remains unclear. There is some evidence that CD8+ T lymphocytes infiltrating the epidermis and dermis act as effector agents against keratinocytes, but the target antigens are unknown [4].

### Prognosis

Spontaneous remission of cutaneous LP treated with various treatment regimens after 1 year occurs in two-thirds of cases [5]. Patients mainly complain of pruritus and residual pigmentation. Oral LP is a chronic disease and usually does not resolve spontaneously [6]. Erosive LP can be extremely painful, and the most severe form can lead to weight loss. A 1% incidence of squamous-cell carcinoma has been reported among patients with oral LP; however, the true risk remains controversial [7]. Nail or scalp involvement may result in irreversible scars, and genital, esophageal, and conjunctival strictures and fibrosis [1].

### Diagnostic tests

LP histopathology consists of a dermoepidermal papule with hyperkeratosis, hypergranulosis, and acanthosis, basal cell vacuoli-

zation, and a band-like inflammatory infiltrate in the superficial dermis.

### Treatment

The aim of treatment depends on the clinical form, severity, and therapeutic response of LP. For cutaneous LP, the aim of treatment is to reduce pruritus and time to resolution, without inducing severe side effects. Asymptomatic oral LP does not usually require treatment. Symptomatic oral LP may need aggressive treatment to stop pain and obtain a remission. The aim of treating nail, scalp, or erosive genital LP is to stop the inflammatory process as soon as possible to avoid scarring.

### Relevant outcomes

Relevant outcomes in cutaneous LP include patient-reported pruritus intensity and clearance of cutaneous lesions assessed by both clinicians and patients. For oral LP, relevant outcomes are quality of life, patient-reported pain, and evaluation through a validated measure assessed by physicians. In oral LP, the rate of recurrence is high after withdrawal of treatment. The recurrence rate and the tolerance of long-term treatment should be considered. These relevant outcomes were mostly not evaluated in the studies reviewed, which commonly used global evaluation scores [8,9].

### Methods of search

We searched the following databases: Medline, Embase, and the Cochrane Central Register of Controlled Trials (CENTRAL) and Cochrane Database of Systematic Reviews in the Cochrane Library until August 8, 2012, using the key words "lichen planus".

## Questions

### Do corticosteroids improve cutaneous lichen planus?

#### Efficacy

One randomized controlled study (RCT) compared the efficacy of oral prednisolone, 30 mg/day, and placebo administered for 10 days in 38 patients [10]. Ten out of 38 patients did not complete

the study; repartition per group, reasons and number of analyzed patients were not described. The median time for LP to clear was 18 weeks in the prednisolone group and 29 weeks in the placebo group ( $P = 0.02$ ). Pruritus at 6 weeks was reported as not statistically different in the two groups. Two patients in the corticosteroids group experienced a severe relapse after treatment withdrawal.

One randomized, unblinded study compared the efficacy of calcipotriol ointment and betamethasone valerate ointment applied twice daily in 31 patients. No differences were observed between the treatments [11]. The side effects of oral prednisolone were minimal [10].

### Implications for practice

Short courses of systemic corticosteroids are usually recommended as first-line treatment for moderate to severe cutaneous LP, although this is not based on relevant clinical trials and recurrences are possible after treatment withdrawal. Topical corticosteroids are recommended as first-line treatment in mild to moderate cutaneous LP. Topical calcipotriol is not recommended.

Although they are widely used, the evidence for corticosteroid efficacy is scant. The poor quality of reporting and the high rate of withdrawn patients in the systemic corticosteroids trial, the absence of blind evaluation, and small size of the calcipotriol trial do not allow any conclusions to be drawn regarding the efficacy of these treatments.

### Do retinoids improve cutaneous lichen planus?

#### Efficacy

We found one RCT evaluating the efficacy of oral retinoids in cutaneous LP [12]: acitretin 30 mg/day versus placebo for 8 weeks in 65 patients. Of the patients in the acitretin group, 64% (18 of 28) improved significantly or had remissions, versus 13% in the placebo group. Tolerability was considered to be good or very good in 73% of the patients [12]. Side effects noted in this study were mainly cheilitis and dry mouth. The most severe side effect of retinoids is teratogenicity.

### Implications for practice

In the relevant RCT neither the duration of the disease before inclusion nor the extent of the lesions were detailed. The criteria for remission and marked improvement were not defined. Furthermore, visible adverse effects of retinoids could have compromised the blinding evaluation [12]. The level of evidence of acitretin efficacy is therefore of average quality.

Because of potential side effects, acitretin is recommended as a second-line treatment for cutaneous LP. Acitretin may also be combined with psoralen-ultraviolet A (PUVA) therapy (see photochemotherapy section that follows).

### Does photochemotherapy improve cutaneous lichen planus?

#### Efficacy

We found a small controlled trial in which 10 patients with cutaneous LP were treated with PUVA therapy on one side of the body [13]. Five out of 10 patients cleared completely on both sides (complete clearance on the first treated side of the body was expected before treating the other side). Patients had a complete response on one side within a mean of 6 weeks.

We did not find RCTs assessing the efficacy of UVB phototherapy. In the largest retrospective, observational study involving 50

patients, 70% of treated patients with narrowband ultraviolet B (UVB) had a complete response within a mean of 11 weeks [14].

No adverse effects were described in the PUVA or UVB trials. Little risk of photoaging or skin cancer exists if the treatment is limited to one or two cycles. This treatment could increase the risk of residual hyperpigmentation in dark-skinned patients.

### Implications for practice

In view of the high rate of spontaneous remission, the evidence for the efficacy of PUVA and UVB TL-01 therapy is weak. Combined treatment with retinoids and PUVA is occasionally recommended, but the efficacy has not been evaluated.

PUVA therapy and UVB TL-01 could be an alternative to oral corticosteroids in moderate to severe cutaneous LP.

### Does griseofulvin, hydroxychloroquine, or sulfasalazine treatment improve cutaneous lichen planus?

#### Efficacy

Two RCTs ( $n = 38$ ,  $n = 48$ ) compared griseofulvin 500 mg/day versus placebo [15,16] and one ( $n = 80$ ) versus hydroxychloroquine 400 mg/day [17]. One RCT compared sulfasalazine maximum 2.5 g/day with placebo [18].

The two trials comparing griseofulvin with placebo and the one comparing griseofulvin with hydroxychloroquine did not report adverse effects. No severe adverse effect was observed in the sulfasalazine trial; however, this treatment has on occasion been associated with life-threatening adverse reactions such as Stevens-Johnson syndrome and pancytopenia.

### Implication for practice

Because of the important discrepancy between trials for cure rate varying between 5 and 80%, unclear risk of bias of the trials, and phototoxic potential, griseofulvin is not recommended for treatment of cutaneous LP. Because of the potential life-threatening adverse reaction, sulfasalazine is not recommended for treatment of cutaneous LP.

### Does methotrexate improve cutaneous lichen planus?

#### Efficacy

There is no RCT assessing the efficacy of methotrexate in LP. We found one retrospective ( $n = 11$ ) [19] and one prospective series ( $n = 24$ ) [20]. Methotrexate was given orally 15–20 mg/week. A complete response was obtained in 10/11 patients after a median of 9.6 weeks of treatment and a cumulative dose of 65–260 mg in the first series [19]. In the prospective series, a complete remission was observed in 14/24 patients at 24 weeks with a cumulative dose of 210–360 mg [19]. In the retrospective series, the only clinical or biological adverse effect observed was nausea and fatigue in one patient, leading to methotrexate withdrawal [19]. In the prospective series, adverse effects were observed in 12 patients (50%): reduced appetite, decrease in hemoglobin, and liver function abnormalities. One patient withdrew [20].

### Implication for practice

Methotrexate by analogy with other cutaneous disease could be used as third-line treatment of generalized LP in case of failure or contraindication to systemic corticosteroids, retinoids, and phototherapy. In the absence of a comparator in a disease known for spontaneous relapse, a spontaneous remission cannot be excluded.

## Do topical corticosteroids improve oral lichen planus?

### Efficacy

#### *Fluocinonide*

We found one RCT [21], in which fluocinonide in an adhesive base, applied six times per day, was compared with its vehicle in 40 patients with oral LP. At 9 weeks the difference significantly favored treatment.

#### *Betamethasone valerate*

One RCT [22] compared betamethasone valerate aerosol, four sprays per day, with placebo in 23 patients with oral LP. At 2 months, eight of 11 patients had a “good or moderate” response in comparison with two moderate responses in the placebo group.

In the two RCTs, the only adverse effect observed was a case of oral candidiasis.

### Implication for practice

Two studies including patients with oral LP of varying degrees of severity provide a low level of evidence for the efficacy of topical corticosteroids in oral LP.

One conclusion of the recently updated Cochrane review on symptomatic oral LP is: “we identified no RCTs that compared steroids with placebo in patients with symptomatic OLP. From the trials in this review there is no evidence that one steroid is any more effective than another” [9]. Despite the absence of evidence, topical corticosteroids are the first-line treatment for oral LP based on clinical practice.

## Do systemic corticosteroids improve oral lichen planus?

### Efficacy

One RCT compared the efficacy of topical triamcinolone with oral betamethasone (5 mg/day for 3 months, followed by a slow taper during 3 months) [23]. No difference for number of patients with improvement of signs and symptoms was observed between the two groups.

Seven patients in the group treated with oral prednisone developed cushingoid features, and one developed diabetes mellitus. Five of patients treated locally developed oral candidiasis [23]. The risk of detection bias considering that outcomes were subjective is high for this unblinded RCT [23].

### Implication for practice

Although systemic corticosteroids are widely used in oral LP, their efficacy has not been documented. Based on clinical practice, systemic corticosteroids 0.5–1 mg/kg are recommended as second-line treatment for erosive oral LP in the absence of response to topical corticosteroid treatment and as first-line treatment in severe oral LP.

## Do retinoids improve oral lichen planus?

### Efficacy

#### *Topical retinoic acid*

We found one RCT ( $n = 20$ ) comparing 0.1% retinoic acid lotion twice daily with placebo in patients with plaque-like LP [24]. After 4 months of therapy, 97% of patients in the tretinoin group had improvement or were cured, in comparison with 21% in the placebo group. An RCT compared 0.05% retinoic acid with fluocinolone acetonide 0.1%, four applications per day [25]. At week 4, clinical

score improvement was significantly greater for the fluocinolone acetonide group.

#### *Isotretinoin gel*

One RCT compared isotretinoin gel twice daily with excipient alone for 2 months in 20 patients [26]. The improvement in scores was 90% and 10%, respectively.

#### *Tazarotene*

One RCT compared tazarotene gel 0.1% versus placebo in 12 patients with hyperkeratotic oral LP. The clinical score was significantly improved in the treatment group [27].

Only mild local side effects were observed.

### Implications for practice

These RCTs included asymptomatic patients, were at high risk of bias, and included a small number of patients. The concentration of 0.05% used in the only trial comparing topical retinoids with topical corticosteroids is lower than the retinoids concentration usually used (0.1%).

Despite the low level of evidence and mainly based on clinical experience, topical retinoid can be recommended as first-line treatment alone or in association with topical corticosteroids for papular-plaque-like form without ulceration oral LP.

## Do topical calcineurin inhibitors improve oral lichen planus?

### Efficacy

#### *Topical ciclosporin*

We found 2 RCTs comparing the efficacy of topical application of ciclosporin with placebo in 16 and 20 patients, respectively [28,29].

There is a statistically significant difference for reducing pain and clinical signs favoring ciclosporin in these two trials.

#### *Tacrolimus*

We don't find a RCT comparing tacrolimus to placebo.

#### *Pimecrolimus*

Three RCTs comparing pimecrolimus cream 1% applied twice daily during 4 weeks [30,31] and 30 days [32] in 12 [31] and 20 [30,32] patients respectively to placebo were selected for inclusion in the two recent Cochrane reviews [8,9].

No difference for pain reduction or clinical outcomes was observed in these three trials except for the physician global assessment in one trial [31]. A forth-trial comparing pimecrolimus to placebo was not included in the Cochrane review [9], because it was not stated that all patients were symptomatic at baseline. There was no comparison between groups in this trial, only difference between end and baseline outcome in each group [33].

The only side effect reported with topical calcineurin inhibitors was a local burning sensation. No elevated serum levels were observed. Current FDA labeling states that topical pimecrolimus and tacrolimus should not be given to treat premalignant conditions.

### Implications for practice

Considering that the two trials are small and possess a high risk of bias, the evidence of efficacy of topical ciclosporin is low [9]. There is no evidence of superiority of pimecrolimus over placebo for treatment of erosive oral LP.

A recent Cochrane review states: "There is weak and unreliable evidence that ciclosporin may reduce pain and clinical signs of OLP. There is no evidence that other calcineurin inhibitors reduce pain compared to either steroids or placebo." [9]

Topical ciclosporin, tacrolimus or pimecrolimus are not recommended for the treatment of oral LP.

### **Are calcineurin inhibitors more effective than topical corticosteroids for treating oral lichen planus?**

#### **Efficacy**

##### **Topical ciclosporin**

Three RCTs compared topical ciclosporin, with topical triamcinolone 0.1%. No difference for pain evaluation or rate of clinical improvement was observed in these trials [34–36]. An RCT compared ciclosporin 1.5% and clobetasol propionate ointment 0.025% [37]. Clobetasol was more effective than ciclosporin in inducing clinical improvement (95% vs 65% of the patients). No difference was observed for pain reduction.

##### **Pimecrolimus**

A RCT comparing pimecrolimus cream 1% to triamcinolone acetate paste 0.1% found no difference between the two treatments [38].

##### **Tacrolimus**

Two trials compared tacrolimus ointment 0.1% with clobetasol propionate 0.5% [39,40]. One found a statistically significant difference favoring tacrolimus for pain and clinical score [39], while no difference between treatments was observed in the other [40]. One trial compared tacrolimus ointment 0.1% with triamcinolone acetate paste 0.1%. The rate of healed and improved patients was not different between groups [41].

#### **Implication for practice**

There are no reliable results demonstrating that topical calcineurin inhibitors are more effective than topical corticosteroids in oral LP.

Topical corticosteroids remain the first-line treatment of symptomatic oral LP.

### **Does topical *Aloe vera* improve oral lichen planus?**

#### **Efficacy**

We found two RCTs ( $n = 54$  [42] and  $n = 64$  [43]) comparing topical *Aloe vera* with placebo. Treatment was applied twice daily for 8 weeks and three times daily for 12 weeks, respectively. One RCT [42] found a statistically significant amelioration at the end of the treatment in the *Aloe vera* group for pain and clinical outcome, while another RCT found no difference [43]. A pooled estimate for the mean clinical score was relative risk 1.34 (95% confidence interval, 1.10–1.62) [9].

An RCT comparing *Aloe vera* gel with triamcinolone acetate paste 0.1% applied four times a day during 4 weeks found no difference between the groups [44].

In these three RCTs, neither symptoms nor erosions were required for inclusion, and no severe adverse effects were reported. The *Aloe vera* preparations used were not standardized and only partially described in terms of component [44] (type of *Aloe vera* extract, excipients) and concentration. There is no data on safety for long-term use of topical *Aloe vera* on erosive mucous membranes [44–46].

#### **Implication for practice**

There is weak evidence that *Aloe vera* may reduce the pain of oral LP and improve the clinical signs of disease compared with placebo [9]. Knowledge on safety is lacking. *Aloe vera* is not recommended for oral LP.

### **Does extracorporeal photochemotherapy improve oral lichen planus?**

#### **Efficacy**

We found two prospective series of seven [47] and 12 [48] patients with resistant severe erosive LP for a mean of 6 years [47] and 7.5 years [47], respectively, who were treated with extracorporeal photochemotherapy, two sessions per week. Complete remission was obtained in all patients in one series [47] and nine out of 12 [48] patients in the other after a mean of 24 [47] and 21 [48] sessions, respectively.

A progressive decrease in blood lymphocytes was observed in all patients, but without significant consequences. In one series, treatment was discontinued in one patient because of difficult venous access [47].

An RCT will probably not be carried out in this severe and rare form of the disease. Well-conducted prospective series currently provide the best level of evidence for this therapy.

#### **Implications for practice**

Because of its cost and availability only in a limited number of centers, extracorporeal photochemotherapy should be restricted to severe erosive LP resistant to other treatments. No comparative studies have yet been conducted.

### **Does other treatment improve oral lichen planus?**

#### **Efficacy**

Several new treatments were compared, each one in a single RCT against placebo (curcuminoids [49], hyaluronic acid [50], ignatia [51], purslane [52], lycopene orally [53]) or corticosteroids (intralesional injection of polysaccharide nucleic acid fraction of bacillus Calmette-Guérin or triamcinolone acetate intralesional injections [54], and thalidomide paste versus dexamethasone paste [55]).

Except for lycopene and purslane, no difference was found between any of these treatments and placebo or corticosteroids. Trials assessing efficacy of etanercept (NCT 00568581) and topical rapamycin (NCT 01061853) are ongoing.

No conclusion can be drawn from these trials owing to unclear or high risk of bias [9].

#### **Implication for practice**

None of these treatments are recommended in treatment of oral LP.

### **Does corticosteroids improve genital, nails or scalp lichen planus?**

#### **Efficacy**

There is no RCT assessing the efficacy of treatments in these LP variants.

We found a prospective cohort study of women with erosive vulvar LP. In 71% of patients symptoms were attenuated with 0.05% clobetasol propionate ointment twice daily without complete resolution [56].

For nails LP, we found two retrospective case series [57,58]. Two-thirds of 142 patients treated with intramuscular injection or oral systemic glucocorticoids and/or intralesional injection or topical glucocorticoids during 6 months were cured or had a major improvement. We did not find a large prospective study for lichen

**Table 27.1** Main treatments for cutaneous and oral lichen planus.

Intervention	Recommendations	Formulation and use
<i>Cutaneous lichen planus</i>		
Topical corticosteroids	First-line treatment for limited cutaneous LP	Very potent corticosteroids (clobetasol propionate ointment 0.05%), at night once daily in thickened lesion of cutaneous LP until remission then maintenance therapy  Potent topical corticosteroids can be used in less severe form of LP or during maintenance therapy
Oral corticosteroids	First-line therapy for widespread cutaneous LP	Prednisolone 0.5–1 mg/kg per day until improvement.
Systemic retinoids	Second-line treatment in cutaneous LP	Acitretin 30 mg/day 8 weeks
Phototherapy	Second-line treatment in cutaneous LP	PUVA, or UVB 2–3 times a week, 12 times alone or associated with systemic retinoids
<i>Oral lichen planus</i>		
Topical corticosteroids	First line treatment for symptomatic oral LP	Very potent corticosteroids (clobetasol propionate ointment 0.05%), 3 times daily until remission and then maintenance therapy  Potent topical corticosteroids can be used in less severe form of LP or during maintenance therapy  Soluble prednisolone tablets, 5 mg in 15 mL water for mouthwash 3 times daily for widespread oral LP
Topical retinoids	Second-line therapy for oral LP in papular and plaque-like white forms and in absence of erosive lesions	Retinoic acid or isotretinoin lotion/ gel 0.1%, twice daily
Oral corticosteroids	First-line therapy for severe erosive LP  Second-line therapy for oral resistant to topical corticosteroids	Prednisolone 0.5–1 mg/kg per day until improvement
Systemic immunosuppressive agents	In patients with cortico-dependent or cortico-resistant erosive LP	E.g., azathioprine, mycophenolate mofetil, methotrexate

planopilaris. Topical glucocorticoids, either alone or combined with an intralesional glucocorticoid injection, are considered, mainly based on small series and clinical experience, as the first-line treatment for lichen planopilaris [59,60].

**Summary**

Many drugs and physical treatments have been used in the treatment of LP, but there is a lack of well-designed and large trials. Two recent Cochrane systematic reviews found weak evidence or an absence of evidence to support the efficacy of a specific treatment. This statement included evidence for topical or systemic corticosteroids which are currently considered first-line treatment of LP (Table 27.1).

**Key points**

- LP is a chronic inflammatory disease mainly affecting the skin and oral mucosae. The aims of treatment vary depending on the clinical LP variant. There is a lack of well-designed and large trials comparing the usually recommended treatments with placebo.
- We found no evidence for the efficacy of systemic or topical corticosteroids, although this treatment is usually recommended as the first-line treatment for cutaneous LP.
- We found limited evidence of the efficacy of acitretin and PUVA therapy in cutaneous LP.
- We found limited evidence for the efficacy of topical corticosteroids and topical retinoids in oral LP.
- We found no evidence that topical calcineurin inhibitors are effective and no evidence that they are more effective than topical corticosteroids in oral LP.

# Acute urticaria

**Torsten Schäfer**

Dermatological Practice, Immenstadt, Germany

## Introduction

This chapter deals with the management of a single isolated episode of urticaria (acute urticaria) rather than recurrent episodes observed in chronic urticaria. Discussion is restricted to randomized controlled trials (RCTs). The majority of the RCTs consider the most recently developed drugs. Earlier experimental work with the first antihistamines is not considered because they were not assessed formally in RCTs. It should be noted that many of the reported RCTs have been conducted in emergency departments. It is unclear whether such results also apply to ordinary practice.

## Background

### Definition

Usual synonyms for urticaria are “hives” or “nettle rash,” according to the German term “Nesselsucht,” which focuses on the typical reactions following skin contact with the stinging nettle (*Urtica dioica*).

The primary lesions of this monomorphic exanthematous disease are hives or wheals, which are defined as circumscribed white- to pink-colored compressible skin elevations produced by dermal edema. Accompanying erythemas in the surrounding area are typical. Pathophysiologically, the wheal can be characterized by local vasodilatation and increase of permeability of capillaries and small venules, followed by transudation of plasma constituents into the papillary and upper reticular dermis. Among a large number of substances, such as kinins, leukotrienes, prostaglandins, or proteolytic enzymes, histamine is the best known elicitor of typical wheal-and-flare reactions. Eruptions of urticarial lesions are usually associated with intense pruritus.

Although the disease may be easily diagnosed from a clinical point of view, standardized or validated diagnostic criteria for urticaria do not exist. The disease is classified by etiology or course.

### Incidence/prevalence

Valid population-based estimates on the incidence of acute urticaria are lacking. Approximately 20–30% of the general population experience at least one episode of urticaria in their life. There is

some consistency in the assumption that acute urticaria is more common in children. Females predominate in acute and chronic forms of the disease [1].

### Etiology

In principle, the same etiological considerations as for chronic urticaria apply. In correspondence with the course of the disease, (acute) infections alone or in combination with concomitant drug intake were found to be associated with acute urticaria in 30–50% of cases [2].

### Prognosis

By definition, acute urticaria is restricted to an occurrence of no longer than 6 weeks, otherwise it will be classified as chronic urticaria. The disease is therefore considered to be self-limiting.

### Diagnostic tests

In principle, the same diagnostic considerations as for chronic urticaria apply. However, a full diagnostic workup is rarely indicated in acute cases. A carefully taken history will provide important etiological hints (infection, drugs).

### Aims of treatment

The aims of treatment are to reduce symptoms or to shorten the course of the disease.

### Relevant outcomes

- Intensity of subjective symptoms (pruritus, sedation);
- disease/wheal intensity;
- general physicians' and patients' assessment as assessed by a numeric scale or a visual analogue scale (VAS);
- surface area (rule of nine);
- cessation rate.

### Methods of search

Any RCT or meta-analysis, systematic review, or Cochrane review on “acute” and “urticaria” or “hive” or “wheal” or “nettle and rash” in the electronic databases PubMed, CENTRAL, and CDSR of the Cochrane Library up to August 2012 were searched. We did not

include studies with healthy volunteers or on experimentally induced histamine reactions.

## Questions

### Which drugs are efficient and safe in the treatment of acute urticaria?

The search of the Cochrane Library and the other electronic databases revealed a recent systematic review on the use of histamine H<sub>2</sub>-receptor antagonists for urticaria by Fedorowicz *et al.* [3]. They included the RCTs of Runge [16], Pontasch [14], Watson [13], and Lin [15], which are described in this chapter as well. A consensus report on the management of urticaria appeared as a result of a panel discussion during the clinically oriented European Society for Dermatological Research's symposium *Urticaria 2000* [4]. Besides the elimination of eliciting stimuli, nonsedating H<sub>1</sub> antihistamines were recommended as standard and initial treatment, with prednisolone 50 mg/day for 3 days as alternative treatment. A further review, which appeared in 2001, describes the evidence-based evaluation of antihistamines in the treatment of urticaria [5]. The paragraph on acute urticaria discusses two studies, which will also be

presented in this chapter [2,6]. Other reviews appeared in 2002, 2003, and 2004 but did not refer to other RCTs than those mentioned in the following [7–9].

Recently, a European consensus guideline on urticaria was published, which also applied methods of evidence-based medicine (systematic literature search, standardized critical appraisal, levels of evidence, and grades of recommendation) [10]. Concerning acute urticaria, nonsedating, second-generation, H<sub>1</sub> antagonists were recommended (grade of recommendation D) based on two publications on loratadine [2] and ceterizine [11] (both level of evidence 2– and low methodological quality). The latter trial was designed to prevent rather than to treat acute urticaria.

Nonresponsive patients should receive either oral corticosteroids as prednisone, 2 × 20 mg/day for 4 days [12] or prednisolone (50 mg/day for 3 days) [2] or alternatively H<sub>2</sub>-blockers (single dose for 5 days) [6,13,14]. Based on levels of evidence 2– and 2+ and a weak methodological quality of one study [2], these therapeutic alternatives were consented with grade D of recommendation.

With respect to single RCTs, the Cochrane Library listed seven such trials with acute urticaria as primary endpoint of the intervention and not as a reported side effect. Three further trials were identified in PubMed. These trials are summarized in Table 28.1.

**Table 28.1** Summary of data from RCTs of the treatment of acute urticaria.

Reference	Intervention	Outcome measures	No. patients enrolled	Results
Moscato and Moore [6]	Single-dose cimetidine 300 mg IM or diphenhydramine 50 mg IM	Itching, wheal intensity, sedation, wheal extent, overall improvement on a 3–4-point numerical scale; validity and reliability not known	93 No dropouts	No difference for clinical response Diphenhydramine significantly more sedating
Watson <i>et al.</i> [13]	Single-dose H <sub>2</sub> -receptor antagonist famotidine 20 mg IM vs H <sub>1</sub> -receptor antagonist diphenhydramine 50 mg IM in the treatment of acute urticaria	Pruritus (patient, VAS) Intensity of urticaria (physician, VAS) Surface area (physician, rule of nine) Sedation (patient, VAS)	25 No dropouts	Only within-group comparison (before/after comparison)
Lin <i>et al.</i> [15]	Diphenhydramine 50 mg + ranitidine 50 mg vs diphenhydramine 50 mg + placebo	Presence of urticaria at baseline and after 1 and 2 h	Unclear	Presence of urticaria after 2 h: 16.2% vs 8.3% (+ ranitidine) <i>P</i> = 0.02
Runge <i>et al.</i> [16]	Single-dose diphenhydramine 50 mg + placebo IV or cimetidine 300 mg + placebo IV or diphenhydramine 50 mg + cimetidine 300 mg IV	Extent (number of involved areas) VAS (110 mm) to assess: pruritus – throat tightness and facial swelling (patient) urticaria – pharyngeal tissue swelling and facial swelling (physician) Change of 25 mm considered clinically significant Adverse effects	39	More urticaria patients receiving diphenhydramine + cimetidine (11/12) experienced relief compared with those receiving diphenhydramine (5/11, <i>P</i> = 0.027) or cimetidine (8/10, ns) alone
Simons [11]	Oral cetirizine 0.25 mg/kg twice daily vs placebo over 18 months in children with atopic eczema	Incidence of diary-reported symptoms typical for acute urticaria	795	Cumulative incidence of urticaria 16.2% vs 5.8% during 18-month treatment ( <i>P</i> < 0.001) 4.6% vs 3.0% during 6-month follow up (ns)
Pollack and Romano [12]	Single-dose diphenhydramine 50 mg IM followed by oral hydroxyzine 25 mg every 4–8 h plus oral prednisone 20 mg twice daily for 4 days or placebo	Pruritus (VAS 10 cm) Adverse effects	43	Significantly more improvement with the addition of steroid
Zuberbier <i>et al.</i> [2]	Loratadine 10 mg/day until remission vs prednisolone 50 mg/day for 3 days followed by loratadine 10 mg/day until remission	Cessation of whealing	109	Percentage cessation at 5 time points Significant differences only after 3 days (when the intervention arm had received prednisolone only so far) (93.8% vs 65.9%)

ns, not significant; IV, intravenous; IM, intramuscular.

### Antihistamines (first-generation H<sub>1</sub> antagonists and H<sub>2</sub> antagonists)

Four studies compared the use of H<sub>1</sub> and H<sub>2</sub> antagonists or a combination. None of these studies had a placebo arm. Two studies compared diphenhydramine with an H<sub>2</sub> antagonist (famotidine or cimetidine).

Moscatti and Moore investigated the efficacy of a single-dose of intramuscular cimetidine 300 mg with intramuscular diphenhydramine 50 mg in 93 young adults [6]. Both treatments yielded significant reductions in itching, wheal intensity, and extent after 30 min, with no differences between treatments. A significant increase in sedation was reported by patients in both groups, but was significantly higher in patients treated with diphenhydramine. Absolute changes in the three- and four-point scoring scales appeared to be clinically important. The study is limited by flaws in the process of randomization and blinding.

Watson *et al.* compared single-dose intramuscular diphenhydramine 50 mg with intramuscular famotidine 20 mg in 25 adults [13]. After 30 min, pruritus was reduced significantly by both treatments, with diphenhydramine appearing more effective. Famotidine also significantly reduced the affected body surface area. Physician-rated intensity of urticaria was reduced equally and significantly by both drugs. A nonsignificant increase in sedation was reported by patients receiving diphenhydramine. The small sample size and unbalanced group size (diphenhydramine  $n = 10$ , famotidine  $n = 15$ ; no block randomization) do not allow for a meaningful comparison of the groups.

Lin *et al.* compared the efficacy of single-dose intravenous diphenhydramine 50 mg alone or in combination with intravenous ranitidine 50 mg in 91 adults [15]. Significantly more patients receiving the combination therapy (91.7%) were free of symptoms after 2 h compared with those who received diphenhydramine alone (73.8%). After control for baseline extent, the combination therapy was able to reduce the number of involved areas significantly within 2 h. Significantly more additional antihistamines were administered in the diphenhydramine group, however, which may have shifted the effect towards the zero-effect level.

Runge *et al.* studied 39 adults with acute allergic reactions, including urticaria [16]. Fourteen patients received a single dose of intravenous diphenhydramine 50 mg, 12 received intravenous cimetidine 300 mg, and 13 received both preparations. After 30 min, the combination therapy led to significantly higher reduction of urticaria (evaluated using a VAS) compared with diphenhydramine alone. The latter, however, achieved the best results in reduction of pruritus, differences being significant compared with cimetidine. The study is limited by the small sample size and significant differences in mean treatment scores for urticaria between study groups, which were not adjusted for in later analyses.

Pontasch *et al.* compared three oral medication in the treatment of acute urticaria in adults [14]. Seven patients received diphenhydramine, six received famotidine, and another seven received cromolyn sodium. Patient satisfaction was highest with diphenhydramine (6/7), followed by famotidine (3/6) and cromolyn sodium (3/7). Adverse effects were reported in 3/7 treated with diphenhydramine, in 3/6 of the famotidine group, and in one patient who received cromolyn sodium.

### Corticosteroids

The addition of oral prednisone 20 mg twice daily for 4 days to the standard treatment with H<sub>1</sub> antagonists was investigated in 43 adults by Pollack and Romano [12]. The intensity of itch, as scored

on a VAS, was significantly reduced by both regimens after 2 and 5 days of follow-up. However, the addition of prednisone reduced the symptom score significantly more than the standard therapy. Although standard therapy with antihistamines is generally considered sufficient, in selected cases (severity, need to shorten antihistamines) addition of prednisone seems helpful.

Similar, Zuberbier *et al.* showed that prednisolone 50 mg/day for 3 days led to a significantly higher clearing rate (93.8%) after 3 days than therapy with loratadine 10 mg/day in 109 patients [2]. The study may be limited by aspects of design (open, pseudo-randomization by consecutive time periods, differential allocation of possibly pregnant women).

A best-evidence report of 2004 summarizes both studies mentioned above [17].

### Other treatments and nonrandomized trials

An early case series of five patients with acute urticaria following insect stings reported good therapeutic effects of intravenous cimetidine 300 mg initially followed by 300 mg orally four times daily) after ineffective administration of epinephrine (adrenaline), H<sub>1</sub> antagonists, and corticosteroids [18].

A further report investigated the effect of flunarizine, a calcium antagonist, in the treatment of acute urticaria. In this uncontrolled trial, 20 patients received a single 10 mg sublingual dose of flunarizine. After 3 h, 16 patients had improved, with effects being more pronounced for itching than for reduction of wheals. Four patients remained unresponsive and five other patients reported drowsiness as a major side effect [19].

A Chinese publication describes the therapeutic effect of the added ingredient of *Radix angelicae sinensis* in 106 patients with acute urticaria. Unfortunately, the lack of an abstract in English makes it difficult to draw conclusions [20].

### Prevention

The European multicenter study ETAC (Early Treatment of the Atopic Child) investigated the preventive effect of long-term (18 months) administration of cetirizine 0.25 mg/kg twice daily in 1–2-year-old children with atopic eczema and positive family history of allergies [11]. On addition to the primary endpoint (asthma), symptoms typical for acute urticaria were recorded in a diary during the intervention period and a 6-month follow-up. During the intervention period, significantly fewer episodes of acute urticaria (5.8%) were reported in the intervention group compared with the placebo arm (16.2%). This effect did not persist after medication was stopped (3.0% vs 4.6%).

### Harms

On the basis of the available studies on acute urticaria, the major side effect is sedation associated with the first-generation H<sub>1</sub> antagonists. Chapter 29 on chronic urticaria discusses the newer antihistamines.

### Comment: implications for clinical practice

Generally, the available therapeutic evidence for acute urticaria is quantitatively and qualitatively weak. RCTs of the therapeutic efficacy of the second-generation antihistamines are lacking, although one would like to consider these the first choice of therapy based on the studies in chronic urticaria. There is some evidence that the combination of H<sub>1</sub> and H<sub>2</sub> antagonists has additional beneficial effects. A short-term intervention with corticosteroids seems to be superior to a treatment with antihistamines alone, but should be considered in the context of individual needs.

### Key points

- Acute urticaria is a common disease.
- It seems to predominate in children and females.
- The etiology remains mostly unclear, but there is evidence that (acute) infections and concomitant drugs, as well as (food) hypersensitivity, are important elicitors.
- The therapeutic evidence for treatment of acute urticaria is qualitatively and quantitatively poor.
- There is evidence that first- and second-generation antihistamines are effective and that the combination with H<sub>2</sub> antagonists may have additional beneficial effects.
- A short-term intervention with corticosteroids seems to be superior to a treatment with antihistamines alone, but should be considered in the context of individual needs.

# Chronic urticaria

Karsten Weller and Marcus Maurer

Department of Dermatology and Allergy, Charité – Universitätsmedizin Berlin, Berlin, Germany

## Background

### Definition and classification

Urticaria is characterized by the development of wheals (hives), angioedema, or both [1]. Whereas wheals (Figure 29.1) are usually associated with pruritus and resolve within 24 h, angioedema is a deeper swelling of the lower dermis and subcutis, which may be painful rather than itchy and can take up to several days to resolve [1]. Urticaria needs to be differentiated from other medical conditions where wheals, angioedema, or both occur [1]; for example, anaphylaxis, urticarial vasculitis, auto-inflammatory syndromes, or bradykinin-mediated angioedema, such as hereditary angioedema or ACE-inhibitor-induced angioedema.

Chronic urticaria is defined by recurrently appearing signs and symptoms for more than 6 weeks [1]. It is subdivided into chronic spontaneous urticaria (CSU), where symptoms occur spontaneously, and inducible forms (chronic inducible urticaria – CIndU), such as physical urticaria and cholinergic urticaria [1]. In CIndU, specific triggers (e.g., cold contact in cold urticaria) provoke urticaria symptoms. The current classification [1] is shown in Table 29.1. Notably, more than one subform of chronic urticaria can occur in the same patient. For example, CSU is frequently accompanied by physical urticaria such as symptomatic dermographism or delayed pressure urticaria.

Chronic urticaria severely impairs the quality of life of affected subjects. Patients with CSU suffer a comparable degree of impairment in many aspects as patients with severe coronary artery disease waiting for bypass surgery [2]. In comparison with other skin diseases, CSU has been repeatedly shown to be among those disorders associated with a particular strong quality-of-life impairment [3].

### Incidence/prevalence

Chronic urticaria is one of the most frequent skin diseases. Data from the middle of the last century suggest that around every fifth person will experience at least one episode of any type of urticaria during her or his lifetime [4, 5]. In 1972, Hellgren reported a point prevalence of around 0.1% for chronic urticaria in the total population in Sweden [6]. More recent population-based studies reported a point prevalence of 0.6% for CSU in Spain [7] and a period prevalence of 0.8% in 1 year for chronic urticaria in Germany [8]. Women suffer from chronic urticaria about twice as often as men do [3].

The exact incidence and prevalence of CIndU is not well examined. However, its subforms differ considerably in frequency, with symptomatic dermographism and cholinergic urticaria being more prevalent than other subtypes, such as cold urticaria and delayed pressure urticaria. Heat urticaria, solar urticaria, aquagenic urticaria, and vibratory angioedema are rare disorders. The disease activity of all chronic urticaria subtypes can markedly change over time and differ between individual patients. In addition, some inducible forms predominantly occur in certain age groups. For example, cholinergic urticaria has its peak incidence in young adults and, when including also very mild forms, affects up to 20% of people at the end of their 20s [9].

### Etiology

Chronic urticaria is a mast-cell-driven disease. Its signs and symptoms, both in spontaneous and inducible urticaria, develop after the activation and degranulation of skin mast cells and the subsequent release of proinflammatory mediators. Mast cells contain pre-formed histamine, heparin, proteases (e.g., tryptase, chymase) and several cytokines that are immediately released upon activation. But mast cells are also able to rapidly produce and secrete prostaglandins, leukotrienes, and platelet-activating factor (PAF). The released mediators result in sensory nerve activation, vasodilatation, and plasma extravasation as well as lesional cell recruitment [1], thereby leading to the typical urticaria symptoms pruritus, wheals, and angioedema. Whereas the pathogenic mechanisms at the level or downstream of mast cells are well understood, with histamine and its interaction with the H<sub>1</sub>-receptor playing a critical role, the mechanisms of mast cell activation are still largely unknown. An allergic activation with the binding of environmental allergens to skin mast-cell-bound specific immunoglobulin E (IgE) is only very rarely relevant in chronic urticaria. Therefore, it can usually not be classified as an allergic disorder. Instead, reported candidates for causing mast cell activation comprise autoantibodies to IgE or the IgE receptor, IgE autoantibodies directed against autoantigens (autoallergens), complement components such as C5a, as well as neuropeptides (e.g., substance P).

### Prognosis

The natural course of chronic urticaria varies considerably between patients. In most patients chronic urticaria is of long duration, frequently lasting for several years [3]. One of the few studies inves-

<sup>c</sup>For example, after/during physical exercise.

tigating the duration of chronic urticaria in the total population [7] found half of the patients to be symptom free 3 months after onset of disease and four of five patients after 1 year. However, more than 10% still had the disease after 5 years. Several other authors have examined disease duration in CSU in selected populations. Although their data vary greatly, a considerable proportion of patients was found to exhibit a disease duration of more than 5 years [10–13] or even more than 10 years [10, 13].

As of yet, there is no prognostic marker available that helps to predict the individual duration of disease. However, there are some factors that appear to be associated with a long duration of chronic urticaria, such as disease severity, appearance of angioedema, a

combination of CSU with CIndU, and autoreactivity (positivity in the autologous serum skin test (ASST)) [3]. Some physicians believe that symptomatic therapy that results in the complete control of symptoms can shorten the course of disease, but there is no published evidence to support this [3].

### Diagnostic tests and possible underlying causes

The diagnostic workup in patients with chronic urticaria is to (1) exclude differential diagnoses if indicated, (2) exclude severe inflammatory conditions (in CSU), (3) test for the presence of CIndU subforms (based on clues from the history), (4) identify the causes of disease (in severe and/or long-standing CSU), and (5) assess disease activity, disease control, and impact.

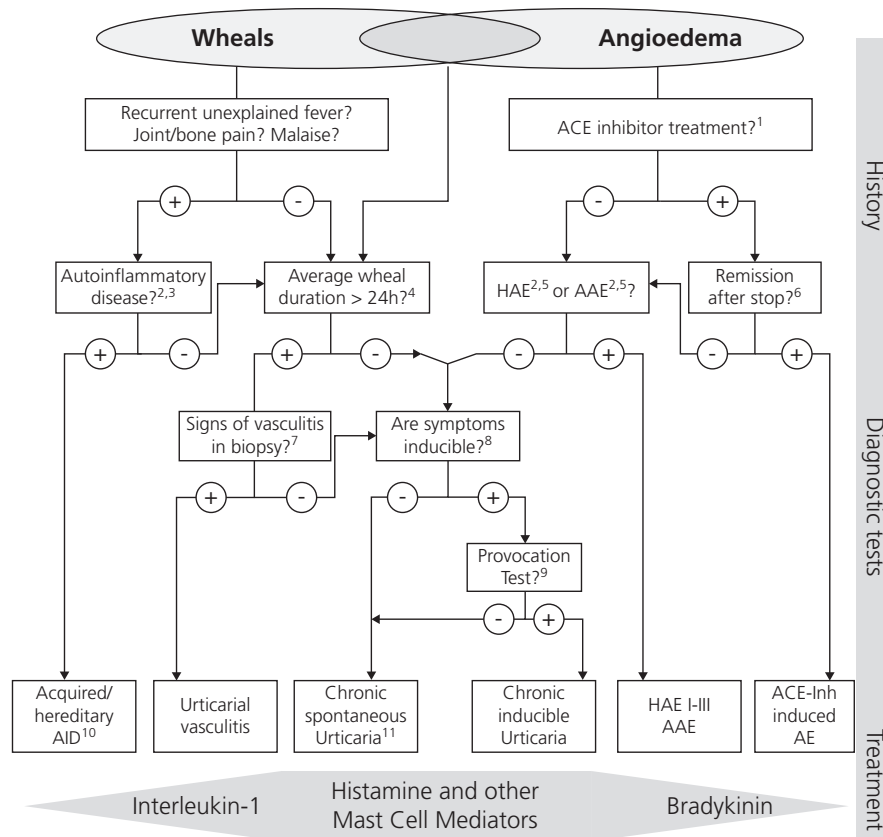

The current EAACI/GA<sup>2</sup>LEN/EDF/WAO guidelines [1] provide a helpful algorithm for the diagnosis and differential diagnosis of patients with chronic urticaria symptoms; that is, wheals and/or angioedema (Figure 29.2).

If the diagnosis of CSU is assured, the general recommendation is to first perform a thorough history and physical examination and to rule out severe systemic disease by basic laboratory tests. These should include a differential blood count and the determination of C-reactive protein (CRP)/ erythrocyte sedimentation rate (ESR). In addition, nonsteroidal anti-inflammatory drugs (NSAIDs) should be omitted [1]. Extended diagnostic procedures should be conducted in patients with long-standing and/or severe disease based on the patient's individual history [1]. Intensive and costly general screening programs are strongly advised against [1]. The current recommendations for diagnostic tests to be performed in chronic urticaria are depicted in Table 29.2.

Common possible causes of CSU include autoreactivity, autoallergy, chronic infections, and intolerance to food components. The frequency of these causes may vary between different geographical regions. Patients with autoreactive CSU are characterized by circulating histamine releasing factors leading to a positive ASST [14]. Around one-third to half of all CSU patients are ASST positive [14, 15]. Some of these patients exhibit autoantibodies against IgE or the high-affinity IgE receptor [14]. High disease activity, poor response to H<sub>1</sub>-antihistamine therapy, and autoimmune comorbidities may point towards the presence of autoreactive CSU. In addition, some CSU patients exhibit IgE antibodies to autoantigen (autoallergens) such as thyroperoxidase [16] and double-stranded DNA [17], and anti-IgE therapy has been shown to effectively control disease in CSU patients with anti-autoantigen IgE [18].

There is a broad consensus that chronic infections with bacteria, viruses, fungi, and helminths are potential causes of CSU [1]. It is possible that infections are either associated with CSU or just coincidence. A causal relationship between an infection and CSU in individual patients will only become clear after specific treatment. There are several reports that demonstrate a clear benefit of CSU patients after eradication of infectious processes [19, 20]. These underlying infections may be asymptomatic or associated with only mild symptoms. In some of these patients no systemic signs of inflammation are detectable.

Intolerance to foods is another common cause of CSU, which must not be mixed up with food allergies that only very rarely underlie the disease. CSU due to intolerance is usually confirmed by a documented improvement of urticaria symptoms during a 4-week pseudoallergen-low diet and by a worsening of disease after oral provocation with the suspected food components. Beneficial effects of a pseudoallergen-low diet have been demonstrated in 32–73% of CSU patients [21–23]. Importantly, the effect of a

**Figure 29.2** Recommended diagnostic algorithm for patients presenting with wheals, angioedema, or both.<sup>1</sup> Abbreviations: AAE, acquired angioedema due to C1-inhibitor deficiency; ACE-Inh, angiotensin converting enzyme inhibitor; AE, angioedema; AH, antihistamine; AID, auto-inflammatory disease; HAE, hereditary angioedema; IL-1, interleukin-1 [24].

<sup>1</sup> Other (new) drugs may also induce bradykinin-mediated angioedema.

<sup>2</sup> Patients should be asked for a detailed family history and age of disease onset.

<sup>3</sup> Test for elevated inflammation markers (CRP, ESR), test for paraproteinemia in adults, look for signs of neutrophil-rich infiltrates in skin biopsy; perform gene mutation analysis of hereditary periodic fever syndromes (e.g., cryopyrin-associated periodic syndrome), if strongly suspected.

<sup>4</sup> Patients should be asked: "How long do your wheals last?"

<sup>5</sup> Test for complement C4, C1-INH levels and function; in addition, test for C1q and C1-INH antibodies, if AAE is suspected; do gene mutation analysis if former tests are unremarkable but patient's history suggests hereditary angioedema.

<sup>6</sup> Wait for up to 6 months for remission; additional diagnostics to test for C1-inhibitor deficiency should only be performed if the family history suggests hereditary angioedema.

<sup>7</sup> Does the biopsy of lesional skin show damage of the small vessels in the papillary and reticular dermis and/or fibrinoid deposits in perivascular and interstitial locations suggestive of UV (urticarial vasculitis)?

<sup>8</sup> Patients should be asked: "Can you make your wheals come?"

<sup>9</sup> In patients with a history suggestive of inducible urticaria, standardized provocation testing according to international consensus recommendations [103] should be performed.

<sup>10</sup> Acquired AIDs (autoinflammatory syndromes) include Schnitzler's syndrome as well as systemic-onset juvenile idiopathic arthritis (sJIA) and adult-onset Still's disease (AOSD); hereditary AIDs include cryopyrin-associated periodic syndromes (CAPS) such as familial cold auto-inflammatory syndromes (FCAS), Muckle-Wells syndrome (MWS) and neonatal onset multisystem inflammatory disease (NOMID), more rarely hyper-IgD syndrome (HIDS) and tumor necrosis factor receptor alpha-associated periodic syndrome (TRAPS).

<sup>11</sup> In some rare cases recurrent angioedema is neither mast cell mediator-mediated nor bradykinin-mediated, and the underlying pathomechanisms remain unknown. These rare cases are referred to as "idiopathic angioedema" by some authors.

pseudoallergen-low diet seems not to be predictable based on patient history.

Other infrequent causes of CSU comprise other chronic inflammatory conditions as well as, very infrequently, sensitizations to type I allergens.

In CIndU the routine diagnosis mainly aims at the identification of the subtype by the appropriate provocation tests and the determination of trigger thresholds [1] (Table 29.2). The latter allows for assessing disease status and response to treatment [1]. The actual

underlying causes of CIndUs, with the exception of contact urticaria, are unknown. Therefore, examinations for causes are not recommended, unless there are compelling clues from the patient history.

In addition, it is important to determine and monitor chronic urticaria patients for disease activity, disease control, and health-related quality-of-life impairment at the beginning and during the course of disease. The currently available and validated instruments for these purposes are shown in Table 29.3.

**Table 29.2** Recommended diagnostic tests in chronic urticaria patients.<sup>a</sup>

Chronic urticaria subtype	Routine diagnostic workup	Extended diagnostic program <sup>a</sup>
Chronic spontaneous urticaria	Differential blood count, ESR or CRP. Omission of suspected drugs (e.g., NSAIDs)	Tests (no preferred order) for infectious diseases (e.g., <i>Helicobacter pylori</i> ), type I allergy; functional autoantibodies; thyroid hormones and autoantibodies, skin tests including physical tests, intolerance by suggesting a pseudoallergen-low diet for 3–4 weeks, tryptase, autologous serum skin test, lesional skin biopsy
Inducible urticarias		
Symptomatic dermographism <sup>a</sup>	Elicit dermographism and perform threshold test (e.g., with a dermatographometer, FricTest device [104])	Differential blood count, ESR or CRP
Cold (contact) urticaria	Cold provocation and threshold test (e.g., with ice cube test or Temptest device [105, 106])	Differential blood count, ESR or CRP, cryoproteins to rule out other diseases, especially infections
(Delayed) pressure urticaria	Pressure test and threshold test (e.g., with weighted rods or dermatographometers). Test result should be read 6 h after testing	None
Solar urticaria	Provocation with UV and visible light of different wave lengths and threshold test (determine test results 15–20 min after provocation)	Rule out other light-induced dermatoses
Heat (contact) urticaria	Heat provocation and threshold test (e.g., with hot water bath or Temptest device [105, 106])	None
Vibratory angioedema	Provocation with vibratory device (e.g., with a laboratory vortex mixer)	None
Cholinergic urticaria	Exercise (e.g., using an ergometer) and/or hot bath provocation	None
Contact urticaria	Provocation test of suspected substance with immediate reading; e.g., prick test	None
Aquagenic urticaria	Cutaneous provocation test with wet cloths at body temperature applied for 20 min	None

<sup>a</sup>Suggested to be based on clues from patient history in order to identify underlying causes or eliciting factors and for ruling out possible differential diagnoses.

**Table 29.3** Available validated and specific tests to determine disease activity, disease control, and disease/symptom-specific quality of life in patients with chronic urticaria.

	Chronic spontaneous urticaria			Inducible urticaria
	Patients with wheals	Patients with wheals and angioedema	Patients with angioedema	
Disease activity	UAS [1, 107]	UAS [1, 107] and AAS [108]	AAS [108]	Determination of trigger threshold with specific provocation test [1]
Disease control	UCT [109]	UCT [109]	UCT [109]	UCT [109]

## Aims of treatment

The aim of treatment is to achieve complete symptom control as safely as possible [1], either by curing patients or by preventing wheal and/or angioedema formation as well as pruritus, and thereby also resolving sleep disturbance and improving patients' health-related quality of life.

## Relevant outcomes

- Level of disease control;
- urticaria activity;
- angioedema activity;

- quality of life;
- interference with sleep;
- interference with daily activities;
- permanent remission.

## Methods of search

A search for clinical studies on “urticaria” was carried out by searching the Cochrane Central Register of Controlled Trials (CENTRAL), the Database of Abstracts of Reviews of Effects (DARE) and the Cochrane Database of Systematic Reviews (CDSR) of the Cochrane Library. In addition, a hand-search was performed.

## Questions

### Which drugs are effective in chronic urticaria?

The updated guidelines [1] published in 2014 revised the recommendations for chronic urticaria management based on the available evidence and suggested an algorithm for the best possible symptomatic treatment approach (Figure 29.3). As first-line therapy, the use of H<sub>1</sub>-antihistamines in standard, licensed dose is recommended. Modern second-generation H<sub>1</sub>-antihistamines should be preferred over first-generation H<sub>1</sub>-antihistamines, because of strong evidence regarding potential serious side effects of the latter. If symptoms persist after 2 weeks, a trial of up to fourfold dosed second-generation H<sub>1</sub>-antihistamines is recommended as second-line therapy. It is also recommended to preferably increase the dose with a single drug instead of combining different H<sub>1</sub>-antihistamines at the same time. If symptoms still persist after a further 1–4 weeks, omalizumab, ciclosporin, or montelukast should be added as third-line therapeutics. There is strong advice against the long-term use of systemic corticosteroids in urticaria, but a short course to control acute exacerbation may be tried. In the following, the currently available evidence for the guideline recommended treatment options are reviewed in detail.

### Efficacy

#### Second-generation H<sub>1</sub>-antihistamines in licensed dose

Second-generation H<sub>1</sub>-antihistamines are the first-line treatment option for patients with all forms of chronic urticaria. They belong to the most frequently taken drugs and generally have a good safety profile. H<sub>1</sub>-antihistamines are currently the only licensed treatment for urticaria together with omalizumab (anti-IgE), and their clinical efficacy and safety is well documented in numerous randomized controlled trials (RCTs). This is clear and accepted and, therefore, not reviewed in detail here. Also, a systematic review of second-generation H<sub>1</sub>-antihistamines in urticaria treatment is forthcoming from the Cochrane Collaboration. Notably, recent reports have demonstrated that second-generation antihistamines in licensed standard doses lead to a complete remission of urticaria symptoms in less than 50% of CSU patients [3, 25]. This is also the experience of the treating physicians in private practice [26] and in the tertiary care setting [27]. In general, patients should be advised to use H<sub>1</sub>-antihistamines continuously rather than on demand, since this has been shown to be the more effective treatment approach in CSU [28] and is also supported by their mechanism of action; that is, that they are inverse agonists of the histamine H<sub>1</sub>-receptor, shifting its conformation towards the inactive state [1]. The dosage in children over 12 years is usually the same as that for adults; the manu-

facturers' recommendations should be followed for children aged up to 12 years.

#### Increasing the dose of second-generation H<sub>1</sub>-antihistamines

An “updosing” of second-generation H<sub>1</sub>-antihistamines is recommended when the standard, licensed dose is not sufficient to achieve symptom control in chronic urticaria patients [1]. For this approach there is currently no systematic review available, but it is supported by several independent RCTs (Table 29.4), four of which [29–32] were performed in CSU patients. Two [30, 32] trials were explicitly done in order to test the efficacy of H<sub>1</sub>-antihistamine updosing. Staevska *et al.* [32] examined 80 patients unresponsive to standard dosed H<sub>1</sub>-antihistamines in a dose escalation, crossover trial with desloratadine and levocetirizine. With licensed doses (5 mg), 13 of 80 patients became symptom free, and an additional 28 of the remaining subjects reportedly showed complete response when treated with up to 20 mg. Seven of these 28 patients showed complete remission only after changing treatment from desloratadine 20 mg to levocetirizine 20 mg. The updosed H<sub>1</sub>-antihistamines did not increase somnolence, and no adverse events (AEs) requiring discontinuation of treatment occurred during the study. In the study of Gimenez-Arnau *et al.* [30], the data of 538 patients from two multicenter RCTs [33, 34], examining rupatadine at the licensed 10 mg or increased 20 mg dose, were pooled and examined for proportions of responders. A reduction of symptoms by at least 75% was observed in 14% of patients treated with placebo and in 35% and 48% treated with rupatadine 10 mg and 20 mg, respectively. The difference between rupatadine treatment and placebo as well as between rupatadine 20 mg and 10 mg was statistically significant. The other two available RCTs in CSU were dose ranging studies applying fexofenadine in doses from 20 to 240 mg twice daily with a total of 876 patients [29, 31]. These studies both found a significant linear trend regarding the reduction of urticaria symptoms with increasing fexofenadine doses. Fexofenadine 240 mg showed the strongest effects in most outcome measures. However, the direct comparison of the higher doses with the regular dose (60 mg twice daily) exhibited no significant differences. A possible reason for not finding stronger effects of updosing in these two trials might be the fact that patients with a history of unresponsiveness to prior H<sub>1</sub>-antihistamine therapy were excluded from participation so that the response to regular dosed H<sub>1</sub>-antihistamines might be overestimated. In both studies, there were no dose-related trends in the incidence of AEs.

Apart from these RCTs, there are two uncontrolled, open-label studies [35, 36] in patients with CSU unresponsive to standard dosed H<sub>1</sub>-antihistamines. While the first of these investigations found only 1 of 20 patients to benefit from an updosing of cetirizine [35], the second study in 21 subjects found the efficacy of 20 mg cetirizine on urticaria symptoms to be significantly better compared with the regular 10 mg dose [36].

Finally, three survey studies assessed the real-life experience with H<sub>1</sub>-antihistamine updosing in physicians of the primary and secondary care levels [26], in physicians of the tertiary care level [27], and in patients [37]. All three reported a higher efficacy of updosed H<sub>1</sub>-antihistamines in CSU patients compared with standard dose treatment.

In addition to these studies in CSU, there are three small RCTs available comparing regular dosed and updosed desloratadine [38, 39] and bilastine [40] in a total of 83 patients suffering from cold urticaria. All three trials found that updosing increased the efficacy of H<sub>1</sub>-antihistamine treatment and was well tolerated.

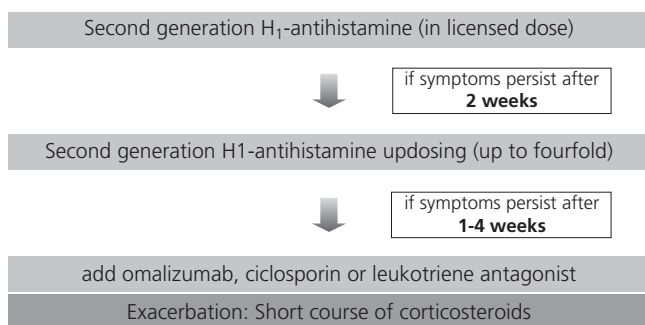

Figure 29.3 Recommended treatment algorithm for urticaria [1].

**Table 29.4** H<sub>1</sub>-antihistamine updosing in chronic urticaria – available RCTs comparing regular licensed doses with higher doses.

Author	Year	Disease examined	Sample size <i>n</i>	Age of patients	Treatment	Treatment duration	Study design	Main results
Krause <i>et al.</i> [34]	2013	Cold urticaria	20	Adults	Bilastine 20 mg vs 40 mg, vs 80 mg, vs placebo	1 week for each dose	Randomized, double-blind, crossover, placebo-controlled, monocenter study	Bilastine 20 mg was effective in reducing the critical temperature threshold. <sup>a</sup> Updosing to 80 mg increased its efficacy. During bilastine, 35% of patients became symptom free during 40 mg and 80 mg 55% and 60%. Bilastine was well tolerated without evidence of increased sedation during dose escalation.
Magerl <i>et al.</i> [38]	2012	Cold urticaria	30	Adults	Desloratadine 5 mg (constant dose) vs 5 mg, 10 mg, 20 mg (dose escalation)	6 weeks	Randomized, double-blind, controlled, dose-escalation, two-center study	Desloratadine 5 mg significantly reduced the critical temperature threshold <sup>a</sup> compared with baseline values (no treatment). Dose escalation resulted in increased efficacy. Complete remission was obtained in none of the patients on 5 mg, while 2 of 15 subjects and an additional 3 of the remaining 13 patients became symptom free on 10 mg and 20 mg. One drug related AE was reported during the trial (mild fatigue during treatment with desloratadine 10 mg).
Staevska <i>et al.</i> [32]	2010	CSU (unresponsive to regular dosed antihistamines)	80	Adults	Desloratadine or levocetirizine in doses of 5 mg, 10 mg and 20 mg (dose escalation depending on efficacy)	4 weeks	Randomized, controlled, double-blind, dose-escalation, crossover, monocenter study	13 of 80 patients became symptom free at the licensed doses and an additional 28 of the remaining patients during up dosing to up to 20 mg. Increased doses went along with an improved quality of life. No AEs occurred requiring discontinuation of treatment, and high dosing did not increase somnolence.
Gimenez-Arnau <i>et al.</i> [30]	2009	CSU	538	Adults	Rupatadine 10 mg vs 20 mg vs placebo	4 weeks	Randomized, double-blind, placebo-controlled, parallel group, multicenter study	A reduction of symptoms by at least 75% during treatment was observed in 14% (placebo), 35% (10 mg) and 48% (20 mg). The differences between 10 mg and placebo as well as between rupatadine 10 mg and 20 mg were statistically significant.
Siebenhaar <i>et al.</i> [39]	2009	Cold urticaria	33	Adults	Desloratadine 5 mg vs 20 mg vs placebo	1 week for each dose	Randomized, double-blind, crossover, placebo-controlled, monocenter study	Desloratadine 5 mg and 20 mg significantly reduced cold-induced urticaria symptoms compared with placebo. Updosing to 20 mg showed higher efficacy than 5 mg treatment. Complete protection of symptoms was found during treatment in 3% (placebo), 23% (5 mg), and 50% (20 mg). No increased rate of somnolence or other AEs occurred during high-dose (20 mg) therapy.
Nelson <i>et al.</i> [31]	2000	CSU	437	12 years and older	Twice-daily fexofenadine 20 mg vs 60 mg vs 120 mg vs 240 mg vs placebo	4 weeks	Randomized, double-blind, dose-ranging, parallel group, multicenter study	Each of the fexofenadine doses was statistically superior to placebo in reducing urticaria symptoms with a mild but significant linear trend for improvement with increasing doses, but in the direct comparison of groups the efficacy results were similar in the 60, 120, and 240 mg treated patients. AEs were reported with similar incidence in all treatment groups (no dose dependency).
Finn <i>et al.</i> [29]	1999	CSU	439	12 years and older	Twice-daily fexofenadine 20 mg vs 60 mg vs 120 mg vs 240 mg vs placebo	6 weeks	Randomized, double-blind, dose-ranging, parallel group, multicenter study	Each of the fexofenadine doses was statistically superior to placebo in reducing urticaria symptoms with a mild but significant linear trend for improvement with increasing doses, but in the direct comparison of groups the efficacy results were similar in the 60, 120, and 240 mg treated patients. AEs were reported with similar incidence in all treatment groups (no dose dependency).

CSU, chronic spontaneous urticaria.

<sup>a</sup>Critical temperature threshold: the minimal eliciting temperature of symptoms.

## Omalizumab

Omalizumab is a humanized antibody targeting circulating IgE. As of yet, no systematic review has been published on its use in CSU, but there are five RCTs [18, 41–44] (Table 29.5) that all found high efficacy of omalizumab in CSU subjects who remain symptomatic despite H<sub>1</sub>-antihistamine treatment in licensed doses [18, 41, 43, 44] or even treatment with H<sub>1</sub>-antihistamines at up to four times the licensed dose plus H<sub>2</sub>-antihistamines, leukotriene antagonists, or both [42]. One RCT was a proof-of-concept study restricted to CSU subjects exhibiting IgE antibodies against thyroperoxidase [18], while the others were performed in CSU patients without a particular pre-screening for autoallergy or autoreactivity [41–44]. The first two RCTs published by Gober *et al.* [41] and Maurer *et al.*

[18] applied the dosing regimen established for omalizumab treatment of severe asthma (depending on the patient's weight and IgE levels), for which it is licensed. Both trials found omalizumab to strongly decrease urticaria symptoms compared with placebo. The study of Gober *et al.* [41] was performed in a limited number of 20 subjects that were treated for 6 months and has only been published as an abstract. In the study of Maurer *et al.* [18], 49 patients received treatment for a period of 24 weeks. At the end of this period, 59% of omalizumab-treated patients were completely free of symptoms compared with 14% in the placebo group. A marked reduction of symptoms appeared already in the first week of therapy with a continuing decrease through week 24. The incidence of suspected drug-related AEs was similar in both treatment groups. No

**Table 29.5** Omalizumab treatment in chronic urticaria – available RCTs.

Author	Year	Disease examined	Sample size <i>n</i>	Age of patients	Treatment	Treatment duration	Study design	Main results
Kaplan <i>et al.</i> [42]	2013	CSU (symptomatic despite treatment with H <sub>1</sub> -antihistamines at up to 4 times the licensed dose plus H <sub>2</sub> -antihistamines, leukotriene antagonists, or both	335	12 years and older	4 weekly omalizumab 300 mg vs placebo	24 weeks	Randomized, double-blind, placebo-controlled, parallel group, multicenter study	Urticaria symptoms and health-related quality of life significantly improved during omalizumab treatment compared with placebo. Complete remission was achieved in 4% (placebo) and 34% (omalizumab 300 mg). Incidence and severity of AEs were similar between both treatment groups. There was no evidence of any clinically meaningful trends in laboratory parameters or vital signs associated with omalizumab therapy and no patient developed anti-omalizumab antibodies.
Maurer <i>et al.</i> [43]	2013	CSU (unresponsive to regular dosed antihistamines)	323	12 years and older	4 weekly omalizumab, 75 mg vs 150 vs 300 mg vs placebo	12 weeks	Randomized, double-blind, placebo-controlled, parallel group, multicenter study	Urticaria symptoms and health-related quality of life significantly improved during omalizumab 150 mg and 300 mg treatment as compared to placebo. The strongest effects were observed for the 300 mg dose. No difference was found between 75 mg and placebo. Complete remission was achieved in 5% (placebo), 16% (75 mg), 22% (150 mg) and 44% (300 mg). Proportions of patients with at least one AE were similar across the treatment groups.
Saini <i>et al.</i> [44]	2011	CSU (unresponsive to regular dosed antihistamines)	90	12 years and older	Single-dose omalizumab 75 mg vs 300 mg vs 600 mg vs placebo	Single-dose treatment, efficacy analysis after 4 weeks	Randomized, double-blind, placebo-controlled, parallel group, multicenter study	Urticaria symptoms significantly improved after 300 mg and 600 mg treatment compared with placebo. No difference was found between 75 mg and placebo. 600 mg had less pronounced effects compared with 300 mg. Complete remission was achieved in 0% (placebo), 4% (75 mg), 36% (300 mg), and 29% (600 mg). The incidence of AEs was similar across treatment groups with the majority of AEs being mild to moderate.
Maurer <i>et al.</i> [3, 18]	2011	CSU with IgE autoantibodies against TPO (unresponsive to regular dosed antihistamines)	49	Adults	Omalizumab 75–375 mg (asthma dosing scheme) vs placebo	24 weeks	Randomized, double-blind, placebo-controlled, parallel group, multicenter study	Urticaria symptoms and health-related quality of life significantly improved during omalizumab treatment compared with placebo. A marked reduction of symptoms was found already in the first week of therapy. Complete remission was achieved in 14% (placebo) and 59% (omalizumab). <i>Safety:</i> the incidence of suspected drug-related AEs was similar between both treatment groups.
Gober <i>et al.</i> [40]	2008	CSU (unresponsive to regular dosed antihistamines)	20	Not reported	Omalizumab (asthma dosing scheme) vs placebo	Not reported	Randomized, double-blind, placebo-controlled, parallel group, monocenter study	Urticaria symptoms and health-related quality of life improved significantly during omalizumab treatment compared with placebo.

AE, adverse event; CSU, chronic spontaneous urticaria; TPO, thyroperoxidase.

clinically meaningful changes in laboratory estimates or vital signs associated with omalizumab were observed. The other three RCTs were performed during the licensing program of omalizumab for CSU. The first published trial was a phase II dose-ranging study in which single doses of 75, 300, and 600 mg omalizumab were used [44]. Urticaria activity significantly decreased in the 300 and 600 mg treated patients when compared with the placebo group, but there was no difference between 75 mg and placebo. Notably, 600 mg omalizumab seemed to have a less pronounced (albeit not statistically significant) effect than 300 mg. Onset of action was detectable again as early as 1 week after administration and continued to improve throughout the trial. The rates of complete remission during treatment were 0% (placebo), 4% (75 mg), 36% (300 mg), and 29% (600 mg). The incidence of AEs was similar across treatment groups, and most were considered to not be related to the study drug. No serious AEs (SAEs) were observed during the treatment phase, and there were no reported observations of anaphylactic reactions or injection site reactions. The fourth and fifth RCTs were both phase III trials. In the study of Maurer *et al.* [43], omalizumab doses of 75, 150, 300 mg or placebo were administered in 4-week intervals for a period of 12 weeks followed by 12 weeks' follow-up. Urticaria symptoms and quality of life improved significantly in the 150 and 300 mg treatment group compared with placebo, but there was, again, no difference between 75 mg omalizumab and placebo. The largest decrease of symptoms was found in the 300 mg group. Percentages of patients with one or more AEs were similar across the treatment groups. Regarding SAEs, there were five in the 300 mg group, two in the placebo group, and one each in the 75 mg and 150 mg groups, with most SAEs in the 300 mg group reported during the follow-up phase. Again, no anaphylactic reactions were observed. Finally, the study of Kaplan *et al.* [42] compared omalizumab 300 mg and placebo administered in 4-week intervals over a total period of 24 weeks followed by 16 weeks' follow-up. Only patients who remained symptomatic despite treatment with H<sub>1</sub>-antihistamines at up to four times the licensed dose plus H<sub>2</sub>-antihistamines, leukotriene antagonists, or both qualified for inclusion. As in the previous RCTs, urticarial symptoms were found to strongly decrease during omalizumab therapy compared with placebo along with a significant quality-of-life improvement. Moreover, a significantly greater number of patients in the omalizumab group became completely symptom free (34%) compared with the placebo group (5%). Omalizumab was effective irrespective of the concomitant therapy of the patients used. During follow-up, the symptoms in patients returned to placebo values, which was also found by Maurer *et al.* [43], indicating that omalizumab is a symptomatic rather than a curative treatment.

In addition to these RCTs there are two small uncontrolled studies in patients with autoimmune CSU [45] or non-autoimmune CSU [46]. In the patients with autoimmune CSU [45] omalizumab was dosed according to the established asthma scheme, while the study in non-autoimmune CSU [46] applied 300 mg omalizumab in different intervals. Both studies found a strong reduction of urticaria symptoms during therapy. Also, the onset of action was found to be early after administration, as early as 48 h in some patients.

The RCTs and uncontrolled studies in CSU are complemented by numerous case series [47–60], some with more than 50 [56] or even 100 patients [53], and several case reports [61–67]. Taken together, these reports suggest that, in the case of complete remission of symptoms, CSU usually goes into remission on day 1 after the first injection and relapses within 2–8 weeks after the last

administration [56], that the majority of CSU patients on omalizumab are able to stop all concomitant CSU medications and remain asymptomatic treated with omalizumab alone [53], that omalizumab might be continued during pregnancy if inevitable [67], that maintenance of long-term remission is possible with omalizumab [63], and that omalizumab seems to be also effective in patients suffering from isolated angioedema [58]. In addition, there are case series [57, 68, 69] and case reports [70–78] available that have been performed in subjects with almost all inducible forms of chronic urticaria suggesting that omalizumab is also effective in many but not all individual patients [73, 77] with CIndU.

### Ciclosporin

A systematic review of ciclosporin in chronic urticaria is not available, but ciclosporin therapy in CSU was examined in three RCTs (Table 29.6) [79–81]. All of these studies were performed in adult patients unresponsive to antihistamines with starting doses of 4–5 mg/kg body weight daily. Two included only ASST-positive subjects [79, 80]. All three RCTs reported a significant improvement of patients during ciclosporin treatment. The proportion of patients showing marked improvement or full remission ranged from 42% to 50%. Notably, the onset of action of ciclosporin was found to be fast in most patients; that is, within 1 week after the initiation of treatment [79, 80]. Side effects were reported with variable frequency. In the study of Grattan *et al.*, 29 of 30 patients receiving ciclosporin reported side effects but these were not severe enough to require withdrawal [80]. Vena *et al.* [81] found AEs in 44 of 64 ciclosporin-treated subjects, of whom four discontinued therapy. In the study of Di Gioacchino *et al.* [79] ciclosporin was well tolerated with no dropouts related to relevant or irreversible side effects. However, the dose had to be reduced in three patients because of mild increases of serum creatinine levels, and four patients reported mild, transient side effects during the first 2 weeks of treatment.

In addition to these RCTs there are several uncontrolled studies [82–86] available in adult CSU patients only poorly responding to H<sub>1</sub>-antihistamines that also found good responder rates to ciclosporin therapy (between 30 and 100%). Four of these uncontrolled trials [82, 83, 85, 86] were performed with low doses of ciclosporin (3 mg/kg body weight or lower), thus suggesting that low-dose treatment may also be effective in CSU. This is particularly important when long-term ciclosporin treatment is considered. Regarding the side effect profile, the uncontrolled studies found comparable results to the RCTs. For ciclosporin therapy in children with CSU there is one case series available [87]. This demonstrates good efficacy and tolerability in seven children aged 9–16 years, with all showing a cessation of hives under a dose of 3 mg/kg body weight.

As in all other treatment options, the necessity for continued ciclosporin application should be reevaluated every 3–6 months [1]. There is no general recommendation on a maximum treatment duration in chronic urticaria, but the possible development of long-term side effects such as nephrotoxicity and increased risk for non-melanoma skin cancer need to be considered.

### H<sub>1</sub>-antihistamines plus leukotriene antagonists

A leukotriene antagonist may be added to H<sub>1</sub>-antihistamine treatment if monotherapy of the latter is not sufficient to control chronic urticaria symptoms. However, there is, as of yet, no systematic review on this approach, and the available evidence is inconclusive. Four RCTs have been performed in CSU [88–92] (Table 29.7) examining add-on therapy of leukotriene antagonists. Two of these

**Table 29.6** Ciclosporin treatment in chronic urticaria – available RCTs.

Author	Year	Disease examined	Sample size <i>n</i>	Age of patients	Treatment	Treatment duration	Study design	Main results
Vena <i>et al.</i> [81]	2006	CSU (unresponsive to regular dosed antihistamines)	99	Adults	Ciclosporin 5 mg/kg starting dose vs placebo (dose reduction after 2 and 4 weeks to 4 mg/kg and 3 mg/kg, co-treatment with cetirizine 10 mg)	16 or 8 weeks	Randomized, double-blind, placebo-controlled, parallel group, multicenter study	Urticaria symptoms and health-related quality of life improved significantly during treatment with ciclosporin compared with placebo. 60% of patients reported AEs with fewer patients in the placebo group. Elevated serum creatinine was the most commonly reported laboratory abnormality.
Di Gioacchino <i>et al.</i> [79]	2003	CSU (only ASST-positive patients with poor response to antihistamines requiring long-term corticosteroid treatment)	40	Adults	Ciclosporin 5 mg/kg starting dose vs cetirizine 10 mg (ciclosporin dose reduction after 8 weeks to 4 mg/kg)	16 weeks	Randomized, double-blind, controlled, parallel group, monocenter study	After 2 weeks the study had to be opened because of severe urticaria symptoms in 16 patients randomized to the cetirizine group. From that point all patients from the cetirizine group also received the ciclosporin regimen. At the end of 16 weeks' treatment, urticaria symptoms had improved significantly compared with baseline. 50% were in full remission during treatment. Onset of action usually occurred within 1 week. In 3 patients, the dose had to be reduced because of side effects.
Grattan <i>et al.</i> [80]	2000	CSU (only ASST-positive patients with poor response to antihistamines)	30	Adults	Ciclosporin 4 mg/kg starting dose vs placebo (dose reduction during the course of the treatment was performed based on tolerability, co-treatment with cetirizine)	4 weeks	Randomized, double-blind, placebo-controlled, parallel group, multicenter study (followed by an open-label extension)	Urticaria symptoms improved by >75% during treatment in 0% (placebo) vs 42% (ciclosporin) of patients. Onset of action occurred within 1 week. The overall response rate to randomized and/or open-label ciclosporin 65%. 29 of 30 patients receiving ciclosporin reported side-effects. These were not severe enough to require withdrawal.

CSU, chronic spontaneous urticaria; ASST, autologous serum skin test (test for autoreactive CSU); AE, adverse event.

trials were done in patients only poorly responding to H<sub>1</sub>-antihistamines [88, 90]. Di Lorenzo *et al.* [89] and Nettis *et al.* [91] each compared the effects of desloratadine 5 mg monotherapy and a combination of desloratadine 5 mg with montelukast 10 mg daily involving a total of 241 patients. Nettis *et al.* found the combination therapy to be significantly more effective than desloratadine monotherapy, whereas Di Lorenzo *et al.* [89] could not confirm this result. However, they were able to demonstrate that the combination therapy is superior to montelukast monotherapy. A third RCT in 95 subjects compared the effects of cetirizine 10 mg with the combination of zafirlukast 20 mg b.i.d. and cetirizine 10 mg [88] and found the combination to be significantly better in improving urticaria symptoms compared with cetirizine monotherapy. However, a subanalysis revealed that only those subjects with a positive ASST showed a significant benefit from the addition of zafirlukast to cetirizine. The fourth available small RCT looked at the effects of montelukast 10 mg or placebo as add-on to ongoing H<sub>1</sub>-antihistamine treatment. This study found no convincing evidence for an improvement of urticaria symptoms by the addition of montelukast.

In addition to the studies in CSU patients, two small RCTs [93, 94] were performed in 36 and 20 participants with delayed pressure urticaria. These trials showed significant superiority of the addition of montelukast 10 mg to either desloratadine 5 mg or loratadine 10 mg, when compared with monotherapy of the respective H<sub>1</sub>-antihistamine alone. In terms of the safety, none of the RCTs performed revealed any considerable side effects of the leukotriene-antagonist add-on treatment.

In addition to the above-mentioned studies, there are four RCTs [95–98] that examined monotherapy of leukotriene antagonists in CSU [95–97] or in a mixed population of CSU and CIndU [98]. Of the two studies comparing the efficacy of montelukast 10 mg with cetirizine 10 mg, one found superiority of montelukast in reducing urticaria symptoms [97], while in the other 8 of 10 patients had to discontinue montelukast treatment because their urticaria got worse [96]. Of the other two RCTs that both compared leukotriene antagonist therapy with placebo treatment, one found a beneficial effect of montelukast 10 mg on urticaria activity [95] while the other failed to demonstrate a therapeutic effect for zafirlukast 20 mg b.i.d. [98]. Finally, there are two uncontrolled studies that both point towards a beneficial effect of montelukast therapy in CSU [99, 100] and a case report showing efficacy of montelukast in a patient with cold urticaria [101].

### Drawbacks

First-generation H<sub>1</sub>-antihistamines are all sedating. Mistakenly, they are commonly regarded as safe by many laypersons and health-care professionals because of their long-standing use [102]. However, they reduce rapid-eye-movement sleep and impair learning and reduce work efficiency [102]. In addition, they are implicated in civil aviation, motor vehicle, and boating accidents, deaths as a result of accidental or intentional overdosing in infants and young children, and suicide in teenagers and adults [102]. Some exhibit cardiotoxicity in overdose [102].

Systemic steroids are highly effective in chronic urticaria but are characterized by an unfavorable side-effect profile when applied as

**Table 29.7** Leukotriene antagonist treatment in chronic urticaria – available randomized controlled trials on leukotriene antagonist add-on therapy.

Author	Year	Disease examined	Sample size <i>n</i>	Age of patients	Treatment	Treatment duration	Study design	Main results
Kosnik and Subic [90]	2011	CSU (poorly responding to antihistamines)	24	Adults	Add-on montelukast 10 mg vs add-on placebo to ongoing antihistamine treatment	2 weeks	Randomized, double-blind, placebo-controlled, crossover, monocenter study	No clear improvement of urticaria symptoms occurred during montelukast add-on treatment compared with placebo. A subanalysis suggested the possible existence of mild effects only in the most severely affected patients.
Wan [92]	2009	CSU	120	Adults	Hydroxyzine 25 mg plus cetirizine 5 mg b.i.d. vs hydroxyzine 25 mg plus famotidine 20 mg b.i.d. vs hydroxyzine 25 mg plus montelukast 5 mg b.i.d. vs placebo b.i.d.	4 weeks	Randomized, single-blind, placebo-controlled, parallel group, monocenter study	An improvement of urticaria symptoms of at least 25% occurred in 53% of patients during hydroxyzine plus montelukast treatment compared with 0% in the placebo group, 23% in the hydroxyzine plus cetirizine group, and 63% in the hydroxyzine plus famotidine group. Mild to moderate sedation occurred in 6 patients of the hydroxyzine plus montelukast group, in 6 patients of the hydroxyzine plus famotidine group, and in 8 patients of the hydroxyzine plus cetirizine group.
Nettis <i>et al.</i> [93]	2006	DPU	36	Adults	Desloratadine 5 mg vs desloratadine 5 mg plus montelukast 10 mg vs placebo	2 weeks	Randomized, double-blind, placebo-controlled, parallel group, monocenter study	The DPU challenge test reaction as well as the clinical DPU symptoms were reduced significantly by desloratadine monotherapy and the combination with montelukast compared with placebo. Add-on of montelukast to desloratadine reduced both outcomes significantly stronger as compared to desloratadine monotherapy. Complete remission was achieved in 0% (placebo), 27% (desloratadine 5 mg), and 83% (desloratadine plus montelukast). No side effects occurred throughout the study.
Di Lorenzo <i>et al.</i> [89]	2004	CSU	160	Adults	Desloratadine 5 mg vs montelukast 10 mg vs desloratadine 5 mg plus montelukast 10 mg vs placebo	6 weeks	Randomized, double-blind, placebo-controlled, parallel group, two-centre study	No improvement of urticaria symptoms occurred during desloratadine plus montelukast treatment compared with desloratadine monotherapy. Both groups were significantly more efficacious compared with placebo and with montelukast monotherapy. A low incidence of AEs was observed in the study. All AEs were rated as mild.
Bagenstose <i>et al.</i> [88]	2004	CSU (poorly responding to antihistamines)	95	12 years and older	Cetirizine 10 mg vs cetirizine 10 mg plus zafirlukast 20 mg b.i.d.	3 weeks	Randomized, double-blind, placebo-controlled, parallel group multicenter study	Urticaria symptoms improved significantly better during zafirlukast add-on treatment compared with cetirizine monotherapy. In a subanalysis, only those subjects with a positive ASST showed a significant benefit from the addition of zafirlukast to cetirizine. No significant AEs occurred throughout the study.
Nettis <i>et al.</i> [91]	2004	CSU	81	15 years and older	Desloratadine 5 mg vs desloratadine 5 mg plus montelukast 10 mg vs placebo	6 weeks	Randomized, double-blind, placebo-controlled, parallel group, monocenter study	Urticaria symptoms improved significantly during desloratadine monotherapy and the combination of desloratadine with montelukast compared with placebo. The montelukast add-on therapy was significantly more efficacious compared with desloratadine monotherapy. No side effects occurred throughout the study.
Nettis <i>et al.</i> [94]	2003	DPU <sup>2</sup>	20	adults	Loratadine 10 mg vs loratadine 10 mg plus montelukast 10 mg	2 weeks	Randomized, double-blind, controlled, parallel group, monocenter study	The DPU challenge test reaction was completely suppressed (complete remission) during treatment in 80% (loratadine plus montelukast) and 20% (loratadine monotherapy). 20% of patients treated with montelukast plus loratadine reported somnolence.

CSU, chronic spontaneous urticaria; DPU, delayed pressure urticaria; AE, adverse event; ASST, autologous serum skin test (test for autoreactive CSU).

long-term treatment. Therefore, corticosteroids should only be used short term, for acute exacerbations. Since there are adequate alternative treatments available, steroid administration can usually be avoided.

Ciclosporin has been found to be effective in chronic urticaria, but it is well established that side effects such as hypertension, hypertrichosis, elevation of creatinine levels up to renal insufficiency, and dyslipidemia may occur. Patients intended for ciclosporin should, therefore, be selected carefully, as well as examined and monitored accurately before and during treatment. If this is done, ciclosporin is usually well tolerated. In most patients, low to medium doses are sufficient.

In addition, to the guideline-recommended treatments, there are a lot of additional therapies that have been reported to work in chronic urticaria (e.g., dapsone, H<sub>2</sub>-antihistamines, sulfasalazine, methotrexate, and phototherapy) but only have very limited or inconsistent evidence. For further details, please see Zuberbier *et al.* [1]. These options should only be used if all recommended first- to third-line therapies are not sufficient to control the patient's symptoms or are contraindicated or not available. Moreover, such widespread treatment failure should prompt a reevaluation of the urticaria diagnosis. In particular, urticaria vasculitis and autoimmune-inflammatory conditions should be clearly ruled out. On the other hand, some treatment alternatives formerly proposed for chronic urticaria have been shown to be ineffective in double-blind, controlled studies and should no longer be used in the average patient [1]. These include tranexamic acid and sodium cromoglycate in CSU, nifedipine in symptomatic dermographism, and colchicine and indometacin in delayed pressure urticaria [1].

### Comment

The guideline-described treatment algorithm includes all reliable drugs for patients with chronic urticaria; that is, H<sub>1</sub>-antihistamines, omalizumab, ciclosporin, and montelukast. This armory is sufficient to treat the vast majority of patients. All other treatment options can usually be avoided, which will help to obtain a timely improvement of urticaria symptoms in most patients but also to prevent frustration on both the patient's and the physician's side.

### Implications for clinical practice

Chronic urticaria is one of the most frequent skin diseases, commonly associated with a major impairment of the patient's quality of life. The first step in the management should be the correct diagnosis and classification, since the further proceeding strongly depends on the subtype present. In CSU, a search for underlying causes is advisable in patients with long-standing and/or severe disease based on clues from the patient's individual history. In all others, only a basic laboratory is recommended to rule out severe systemic disease. In CIndU, underlying causes are unknown for most subforms. Further diagnosis here mainly aims at the identification of triggers and the determination of trigger thresholds, because the latter allow for assessing disease status and response to treatment.

Whenever possible, chronic urticaria patients should be treated causally. For all other cases, the current guidelines suggest a symptomatic treatment algorithm that does not distinguish between different subforms. The first-line therapies are second-generation H<sub>1</sub>-antihistamines in licensed doses, followed by an up dosing up to fourfold as a second-line option. H<sub>1</sub>-antihistamine therapy is safe and usually well tolerated, if first-generation drugs with sedative side effects are avoided. A continuous dosing schedule should be

preferred over on-demand treatment. Since there is a considerable proportion of patients who not respond sufficiently to H<sub>1</sub>-antihistamines, regardless of which dose is applied, an add-on of omalizumab, ciclosporin, or montelukast may be performed as a third-line treatment. The best evidence is currently available for omalizumab, which has been first licensed in 2014 for the treatment of CSU, where it is highly effective, safe and well tolerated, and has a fast onset of action. In contrast to asthma, the dosing scheme is not dependent on total IgE levels and body weight. Instead, doses of 150 or 300 mg per administration are usually sufficient to achieve good responses. Ciclosporin has also been repeatedly shown to exhibit good efficacy in CSU. However, not all patients qualify for this treatment since several potential side effects and contraindications have to be considered. Consequently, patients have to be carefully selected and monitored. Montelukast has the weakest evidence for efficacy of all third-line therapies, but is characterized by a good safety profile. Systemic corticosteroids may also be used, but only in short courses for acute exacerbations. A long-term treatment with systemic corticosteroids is strongly advised against because of the unfavorable long-term side-effect profile. Since all subtypes of chronic urticaria show spontaneous remission, the need for treatment should be reviewed every 3–6 months.

### Key points

- Chronic urticaria is a common disorder that significantly impairs the patient's quality of life.
- A correct diagnosis and classification of chronic urticaria is important since the management depends on the subtype present, and important differential diagnosis should be excluded.
- In CSU, a search for underlying causes is justified in patients with long-standing and/or severe disease.
- Possible causes of CSU include autoreactivity, autoallergy, chronic infections, and food intolerance.
- In CIndU, underlying causes are unknown for most subforms.
- Diagnosis in CIndU mainly aims at the identification of triggers and the determination of trigger thresholds.
- A causal treatment of chronic urticaria should be performed whenever possible; all remaining patients should be treated symptomatically.
- The aim of symptomatic treatment is complete symptom control.
- A symptomatic treatment algorithm is recommended by the current guidelines; this does not distinguish between different chronic urticaria subforms.
- The first-line symptomatic therapy is second-generation H<sub>1</sub>-antihistamines in licensed dose, followed by an up dosing up to fourfold as a second-line option.
- Third-line treatment options comprise add-on omalizumab, ciclosporin, or montelukast.
- Of the third-line options, omalizumab has currently the best available evidence.
- First-generation, sedating H<sub>1</sub>-antihistamine should not be used, owing to their unfavorable side-effect profile.
- Systemic corticosteroids should only be applied in short courses to manage acute exacerbations.
- All subtypes of chronic urticaria show spontaneous remission. Therefore, the need for treatment should be reviewed regularly every 3–6 months.
- Disease activity, disease control, and impact of chronic urticaria should be examined and/or followed with validated patient-reported instruments, such as the urticaria activity score, angioedema activity score, urticaria control test, chronic urticaria quality of life questionnaire and angioedema quality of life questionnaire.

## SECTION 2 Skin cancer, moles, and actinic keratoses

Robert Dellavalle, editor

### CHAPTER 30

## Primary prevention of skin cancer

Monika Janda<sup>1</sup> and Adèle C. Green<sup>2</sup>

<sup>1</sup>School of Public Health, Queensland University of Technology, Brisbane, Queensland, Australia

<sup>2</sup>Cancer and Population Studies Group, QIMR Berghofer Medical Research Institute, Brisbane, Queensland, Australia

### Background

#### Incidence, mortality, and morbidity of skin cancers

Skin cancer is more common than any other type of cancer in white populations, and keratinocyte (KC) cancers are by far the most common, comprising mainly basal cell carcinoma (BCC) and squamous cell carcinoma (SCC).

BCC and SCC incidence rates are high, around 800/100 000 and 330/100 000 respectively in sunny countries like Australia and lower in temperate climates such as the UK, with rates of around 60/100 000 and 30/100 000 respectively. Incidence of BCC rises with age, but lesions frequently occur in adults before age 50 [1] and are seen on the trunk as well as on the face [2]. SCC is diagnosed predominantly in adults over 60 years on the head and forearms. In the USA in 2006 it was estimated that a total of 2 152 500 people were treated for some 3 507 700 KC cancers [3]. These figures show also that repeated occurrences of primary KC skin cancer are frequent in affected patients. Men usually have

higher incidence rates than women overall, but this can vary by age group, and differences are ultimately thought to reflect sex-specific differences in sun exposure. Though BCCs and SCCs respond well to treatment and have relatively low mortality rates, their high incidence rates mean that their associated health-care costs impose a substantial financial burden on health-care systems [4].

Melanoma is the third commonest but most serious form of skin cancer, with incidence rates varying widely across the globe (Figure 30.1). Melanoma incidence in white Caucasians is around 50/100 000 in Australia compared with around 10/100 000 in the UK, and corresponding mortality rates are 5.7/100 000 and 2.6/100 000 respectively.

While widespread increases in melanoma incidence have been noted in white populations worldwide in the last two to three decades, much of the increase has been ascribed to increased detection of nonfatal melanomas rather than to a true rise in incidence of the disease, since the corresponding melanoma mortality rates have hardly changed over the same period [5].

## Risk factors

### Pigmentation phenotype

Skin cancer is mostly a disease of white-skinned populations [6]; among those of European ancestry, skin cancer incidence is higher among those who have lighter complexions with light hair and eye color, freckling, and a susceptibility to sunburn [7]. In addition, the presence of atypical nevi or having large numbers of common acquired melanocytic nevi raises the risk of melanoma [8,9]. Although the majority of melanomas arise *de novo*, both common and atypical nevi can act as precursors, and around 20–40% of melanomas have histological evidence of a contiguous nevus [10].

### Genetic susceptibility

Xeroderma pigmentosum (XP) patients have an extreme photosensitivity to ultraviolet (UV) radiation as the result of a deficiency in the enzyme for excision repair of UV-damaged DNA and are highly susceptible to all three types of skin cancer. Similarly, variants of the melanocortin-1 receptor (MC1R) gene, indicated by red hair and lack of tanning ability, are associated with increased risk of all types of skin cancer.

Patients affected by Gorlin's syndrome (nevoid basal cell carcinoma syndrome) carry mutations in the *patched* gene, a tumor suppressor gene, and they develop multiple BCCs from an early age [11]. Up to 90% of sporadic BCCs also show *patched* mutations [12]; the *patched* gene product is part of the sonic hedgehog (Shh) protein receptor. It is thought that upregulation of the Shh pathway is the pivotal abnormality in BCCs and little more than Shh upregulation may be needed for BCC carcinogenesis [13]. Family linkage studies have identified three major melanoma susceptibility genes: CDKN2A, ARAF, and CDK4 [14], though of all melanomas newly diagnosed, familial melanoma accounts for fewer than 10%.

### Exposure to the sun and ultraviolet radiation

Epidemiological studies consistently show that white populations who receive low sun exposure rarely develop skin cancer [15,16]. Further evidence of the predominant causal role of solar UV radiation in development of all three types of skin cancer is their consistent association with clinical signs of chronic sun damage [17,18], notwithstanding an overall lack of association with self-reported chronic sun exposure [19,20]. This may be partly due to self-selection of indoor work by sun-sensitive people [20].

The majority of sporadic SCCs carry mutations of the *p53* tumor-suppressor gene [21], with "UV-signature mutations" showing they were caused by exposure to UV radiation. The relationships between sun exposure and BCC and melanoma are complex, however, and interpretation of analytic study findings is frustrated by the difficulty in measuring life-course sun exposure and by the knowledge that sun-related behavior and the biological effects of sun exposure are both highly modified by host factors.

In addition to solar UV, exposure to artificial sources of UV radiation also increases skin cancer risk. The use of tanning devices is associated with a significant increase in BCC [22], SCC, and melanoma occurrence [23], especially with young age at first use. Long-term exposure to phototherapy of oral methoxypsoralen (psoralen) and UV A radiation for psoriasis and other skin conditions has also been shown to increase the risk of developing melanoma [24].

### Early diagnosis

Early diagnosis is the key to reducing deaths from skin cancers in the short term, especially melanoma, as delayed diagnosis increases the risk of mortality. Survival rates have improved greatly in the last

few decades mainly because doctor and patient awareness have increased so that today the majority of melanoma patients are diagnosed with thin melanomas ( $\leq 1.00$  mm) and have an overall 20-year survival rate of 96% [25].

### Aims in primary prevention

Primary prevention involves interventions designed to prevent skin cancer from occurring for the first time. Interventions for primary sun protection aim to change risk behavior (as an intermediate measure) in order to reduce the incidence of skin cancer (as a health outcome measure). The main sun-protection strategies are use of sunscreens, wearing of wide-brimmed hats and clothing cover when outdoors, staying out of the sun between 10 a.m. and 4 p.m., and use of shade. Other interventional approaches to direct primary prevention of skin cancer have been based on chemoprevention.

### Search strategy

Studies included in this chapter were found by searching the Cochrane Library and PubMed. Searches were conducted in May and June 2012. The MESH headings used were Skin Neoplasms/prevention & control\* and Melanoma/prevention & control\*, restricted to reviews, meta-analyses, randomized or controlled clinical trials, and those published in the last 5 years. Where a continuous update was provided for any of the reviews, the latest update was used. While the available reviews used different grading systems for the strength of the evidence, none utilized the strength of recommendations taxonomy (SORT) [26], which we applied to the findings as summarized in Table 30.1, and the findings of the reviews have thus been transferred into SORT measures.

For brevity, where evidence from reviews was available it was used, before randomized trials were sought and summarized.

## Review of evidence on primary prevention

### Behavioral interventions to reduce skin cancer incidence

Clinicians can play an important role in primary prevention of skin cancer. Given the plethora of information now available, patients value clinicians' advice and help to integrate their preferences with the best available evidence [27]. Consultations provide opportunities to support patients' decision-making and to discuss cues for action [28]. While the link between sun exposure behavior and skin cancer incidence is well established, for the vast majority of behavioral interventions evidence is available only for intermediate outcomes such as sunburn or tanning rather than skin cancer incidence or mortality, owing to the long latency of skin cancer development. As exemplified by the model guiding the review of the literature performed by the Community Preventive Services Task Force [29], it is expected that improvements in these intermediate outcomes (i.e., reduction in sunburn, increase in clothing cover, etc.) will lead to better patient outcomes measured by quality of life, incidence, or mortality. Behavioral primary prevention interventions aim to improve personal protection from UV through:

- covering the skin with clothing, hats, or sunscreen for areas of the skin that are not covered by clothing (Figure 30.2);
- protecting the skin around the eyes (and the eyes) with sunglasses;
- staying in shade provided by natural or artificial sources; and
- avoiding sun exposure, especially during peak UV hours.

Kasparian *et al.* [30] summarized the prevalence of current use of these methods, ranging from 4 to 86% for hat, 4 to 70% for cloth-

ing, 16 to 62% for sunglasses use, and 15 to 59% for seeking shade. Sun protection by sunscreen use, reported by 7–90% of people, is complicated by dependence on application thickness, with most people applying about 1 mg/cm<sup>2</sup> providing a sun protection factor (SPF) of about one-third of the sunscreen's advertised SPF [31].

As summarized by the UK National Institute for Health and Clinical Excellence (NICE) guidelines (number 6) [32], behavioral interventions can be delivered through a number of means, including education, counseling by a health-care provider, policy or environmental changes, community-wide engagement through media or social media campaigns, or the simultaneous use of several of these components. For any of these methods, behavioral interventions should follow a set of best-practise rules, including:

- being based on a thorough needs assessment of the target population;

- taking account of existing strength and barriers within the target population;
- applying the latest evidence for effective behavior change;
- being delivered by trained personnel; and
- featuring an evaluation of their effectiveness [32].

Increasingly, intervention programs are guided by health behavior theories, such as the health belief model [33], social cognitive model [34], the preventive health model [35], the theory of planned behavior [36], or the transtheoretical model [37,38]. While these health behavior theories have allowed the development of effective interventions to change peoples' knowledge, attitudes, and intentions, they often fail to similarly influence automatic, affective systems driven by situational factors and social norms [39]. For example, despite knowing that excessive sun exposure is unhealthy, adolescents' fashion norms often lead to deliberate tanning [40]. Modern interventions thus integrate components that specifically target social and motivational barriers [41]. UV photographs highlight solar damage to the skin and skin aging caused by tanning, and so they can provide visual cues to facilitate behavior change [42].

In addition to intervening at the individual level, meso- and macro-level changes to community, national or international appearance norms are also needed before skin cancer prevention is regarded as normative behavior [43].

There are 17 evidence-based programs related to skin cancer primary prevention that are currently listed on the USA National Cancer Institute's research-tested intervention programs website [44], and cancer agencies around the world have developed comprehensive programs such as SunSmart (Australia and UK) and SunWise (USA). In 2004, a systematic review of interventions to reduce skin cancer was published by the Community Preventive Services Task Force [29], which also integrated previous reviews by other agencies (IARC, US Preventive Services Tasks Force (USPSTF), and the US Centers for Disease Control and Prevention).

More recently, a systematic for the USPSTF review has summarized the evidence focusing on behavioral counseling [45,46], and five systematic reviews have been undertaken for NICE. Each of these reviews posed different research questions: the Community Preventive Services Task Force was guided by a conceptual framework for pathways from knowledge, attitudes to behavior change to decrease in skin cancer; the USPSTF review was designed to answer five behavioral counseling-focused questions; while the NICE reviews were guided by a set of broad research questions. An Australian review has provided a comprehensive summary of available evidence since 1980 [30]. One review has focused solely on interventions for outdoor workers [47].

### Interventions directed at individuals

All reviews concurred that educational or behavioral interventions directed at individuals are effective in improving sun protective behaviors, including those directed at parents of newborn children, primary school children, adolescents, and young adults. Recent interventions have commonly included individualized or tailored feedback and appearance-based components such as UV photographs targeting the affective system [29,45,46]. For example, the USPSTF review recommended that behavioral counseling for children, adolescents, and young adults who have fair skin is effective (USPSTF-B – indicating that the USPSTF recommends the services as there is high certainty of moderate net benefit or moderate certainty of moderate to substantial benefit [45]). Similarly, NICE guidelines recommend behavioral counseling of these groups [48] (Table 30.1). With regard to adults, the USPSTF states that the evidence is insufficient to make recommendations either for or against behavioral counseling even though several randomized trials have involved adults. These trials have mostly focused on high-risk groups for either occupational, recreational, or family risk reasons (e.g., beachgoers [49], outdoor workers [50], or relatives of patients with skin cancers [51]). In Manne *et al.*'s study [51], a tailored compared with a generic print and telephone counseling intervention significantly improved sun protection habits among first-degree relatives of patients with melanoma. UV photographs in combination with a cancer-specific or aging-specific video compared with control were effective in increasing sun protection behavior and reducing skin tanning in a high-risk population of outdoor workers [50]. Falk and Anderson [52] randomized adults to a personalized doctor's consultation or a doctor's consultation plus a test of sun sensitivity compared with educational letter-only control. Both groups receiving the doctor's consultation reduced their sun exposure behavior significantly more than the group who received written education only. However, in average-risk individuals the difference in sun protection that can be achieved between groups may be less than in high-risk groups, making statistically significant improvements which could then result in recommendations by agencies less likely.

### Comment

Education and counseling are the cornerstones of health promotion and have been found to be effective in improving intermediate skin cancer prevention outcomes.

### Policy interventions and community mobilization

Policy and environmental interventions aim to promote sun-safe practices by setting standards for expected relevant behaviors and providing the necessary education, supportive structures, and physical means to achieve high sun protection or reduced sun exposure

behaviors. Such interventions have been tested in childcare, school, outdoor worker, and community settings and have been found to be effective in at least some of these settings. The majority of trials have been conducted in primary school settings, and have showed significant improvements of at least 25% in children's sun-protective clothing [29]. The provision of sun-protective policy interventions in outdoor workers was found to increase the prevalence of wearing sun-protective clothing by 11% across several randomized trials [29]. The provision of shade within intervention high schools in Australia resulted in significantly greater use of shade by adolescents compared with shade use in other schools in a cluster randomized trial [53].

Policies are commonly more effective when they are developed together with the community or organizations that must follow the policy [48]. Some policy interventions, such as providing personal protective equipment or shade, can be costly, and NICE therefore only recommends adding shade to new buildings rather than improving existing facilities. NICE recommendations regarding policy interventions have focused on schools and outdoor activity providers as well as high-risk workers (Table 30.1). In addition to implementing the policies that fit with the culture of the community or organization, regular review of the environmental structures, policy documents, and enforcement of policy-compliant behaviors is needed to ascertain continued relevance [54].

### Comment

Policies are useful to set clear and tangible goals and outcome expectations, but to be effective they need to be acceptable to the target audience, supported by key stakeholders, and regularly reviewed for their currency.

### Interventions using media or social media

In the review by the Community Preventive Task Force, 12 reports were identified, but only two measured behavioral outcomes, with neither providing sufficient evidence for the effectiveness of media campaigns alone [29]. As described by Kemp *et al.* [55], mass media can be a valuable component of health behavior communication programs, but consistency of message and competing market forces may limit their reach or intended purpose. The NICE guidelines recommend that health practitioners use low-cost local media campaigns to raise awareness of skin cancer prevention [48]. They also detail recommendations on optimizing (recommendation 3) and tailoring (recommendation 4) message content, including personal and environmental risk assessment. They mention the whole range of options for sun protection and discuss the balance between risks and benefits of sun exposure [48].

### Comment

Few interventions have relied solely on media or social media, and media intervention components are most likely to be integrated into multicomponent interventions as reviewed below.

### Multicomponent interventions

The majority of skin cancer prevention interventions use some combination of education strategies, mass-media campaigns, and environmental policy changes. They usually have a logo and name, a theme, a specific set of messages, and focus on clearly defined geographic areas with specific targets. The Community Task Force Review included studies that had clearly defined geographic boundaries and at least two components in two settings [29]. Comprehensive community-wide interventions are multiple-level

approaches that address large numbers in the given population. Examples include the 20-year “Slip! Slop! Slap!” and SunSmart campaigns in Victoria, Australia [56], and by Cancer Research UK, Sun Pass in Germany [57], the SunSafe project in New Hampshire [58], and the Falmouth Safe Skin Project in Massachusetts [59]. Australia has had the longest-running and most sustained campaigns, and there are indications of slowing skin cancer incidence rates among people over 60 years and a drop in incidence of under 60 years in Victoria, the state with the most sustained investment into SunSmart [60,61].

### Comment

While evidence for a decrease in incidence of melanoma is accumulating, the changes in incidence may take longer to become apparent in populations with lower baseline incidence rates.

### Barriers to sun protection, and risks and harms of promoting sun protection

For the NICE guidelines, two reviews of qualitative research studies specifically summarized barriers to sun protection that need to be overcome in the future [48]. The most prominent ones included perceptions of skin cancer being less serious and more easily treated than other cancers (evidence statement 5.8), perceptions of tanned skin being desirable (evidence statement 5.13), and being indicative of good health (evidence statement 5.15). Specific barriers to each of the sun protection methods were also identified, including cost concerns, allergic or unpleasant skin reaction to sunscreen, and uncomfortable or unfashionable sun protective clothing. Barriers to sun protection in various settings have also been described by NICE [48] and Kasparian *et al.* [30]; for example, child-care workers raised concerns about whether applying sunscreen to children formed part of their roles and responsibilities.

With regard to potential for harm through sun protection, the USPSTF assessed but could find no evidence that counseling about sun protection leads to reduction in physical activity in children [45]. The NICE guidelines considered reductions of physical activity and vitamin D production as potential harms of sun protection [48]. Recent results from the Nambour trial, however, showed no difference in vitamin D levels between participants assigned to daily sunscreen or usual care, and also no difference depending on whether or not participants reported use of various sun protection methods [62]. The only exception was participants who usually or almost always stayed in the shade: on average they had a mean vitamin D level two points below those not usually seeking shade [62].

### Health-economic modeling and evaluation

The NICE report undertook hypothetical economic modeling of three potential interventions. A home-based intervention directed at parents and children provided the most cost-effective intervention with an estimated £6700 per quality adjusted life years (QALY), while interventions directed at school children or young adults and adding shade structures to new buildings resulted in cost per QALY of £20 000–30 000. Estimates were also provided for a mass-media campaign costing £0.0028–0.0093 per person to be cost-effective for increasing the proportion of people using sunscreen by 2–6.6% [48]. Kyle *et al.* [63] provided cost-effectiveness calculations for the US SunWise program and concluded that every dollar invested had the potential to save between \$2 and \$4 in medical and productivity loss costs. Cost-effectiveness analysis of the SunSmart campaign in Victoria, Australia, estimated that based on the change in skin

cancer incidence in Victoria an intensive SunSmart campaign would likely be cost-effective, and prevent more than 100 000 disability adjusted life-years over a period of 20 years [64].

### Preventive interventions with skin cancer as the primary outcome

Several trials of chemoprevention of skin cancer have assessed occurrence of new BCC, SCC, or melanoma as direct outcomes.

#### Sunscreen

Sunscreen application to exposed skin is the most common means of self-protection from the sun in order to reduce acute and/or long-term skin damage. A single community-based skin cancer prevention trial has been conducted in the township of Nambour, Australia [65]. The Nambour Skin Cancer Prevention Trial evaluated daily sunscreen use (together with betacarotene supplementation) in the prevention of BCC and SCC. At the end of the trial, in comparison with people randomized to using sunscreen at their discretion, including nonuse, people randomized to daily use of a broad-spectrum SPF 15+ sunscreen had no reduction in BCC but a 40% reduction in SCC tumors [66], which was maintained 8 years later [67]. Rate of acquisition of actinic keratoses (AKs) was also reduced in the daily sunscreen group [68], as was the time to subsequent BCCs after the first BCC [69] in the trial period, though this finding could have been due to chance. Nambour Trial participants were followed up 10 years after trial cessation for melanoma occurrence. Those allocated to daily sunscreen use showed a 50% reduction in all primary melanomas (at a borderline level of statistical significance), including a substantial reduction in invasive melanomas, compared with controls [70]. This evidence is consistent with findings from a randomized controlled trial among Canadian children allocated to sunscreen application for 2 years who showed a small reduction in new melanocytic nevi compared with controls, especially among children with freckles [71].

### Can other chemoprevention interventions reduce the risk of cancer?

A large proportion of chemoprevention trials have been conducted in subpopulations at unusually high risk of skin cancer because of genetic disorders or immunosuppressive therapy. Since findings regarding preventive efficacy do not concern primary prevention measures that can be applied to the majority of patients at risk of skin cancer, evidence from such trials has not been included here.

#### Micronutrients

In the 1990s, the International Agency for Research on Cancer reported on two separate meta-analyses of vitamin A intake [72] and carotenoids [73] and their effect on cancers, including skin cancer, and concluded that there was no association between either micronutrient and skin cancer. In 2009, a systematic review and meta-analysis of randomized controlled trials reviewed the effect of betacarotene supplementation on cancer incidence, including skin cancers [74], and showed no association with BCC, SCC, or melanoma among the five relevant trials. Similarly, a Cochrane review that reported on two randomized controlled trials that evaluated the efficacy of selenium supplementation for KC cancer prevention found no protective efficacy against nonmelanoma skin cancer [75]. The effects of 400 IU of vitamin D3 combined with 1000 mg of calcium supplementation on skin cancer were assessed post hoc in the Women's Health Initiative randomized placebo-controlled trial among 36 282 postmenopausal women aged 50–79

with 7 years mean follow-up. Only aggregate self-reported KC outcomes were available, but no differences were seen between treatment groups; nor was there any difference in melanoma rates overall, though subgroup analyses in women with history of KC assigned to the vitamin D plus calcium treatment versus placebo had a reduced risk of melanoma not seen in women without a past history of KC.

#### Comment

The evidence from randomized controlled trials suggests that vitamin A, betacarotene, selenium in brewer's yeast tablets, and relatively low-dose vitamin D supplementation plus calcium are not effective in preventing skin cancers.

#### Systemic retinoids

In a past meta-analysis of retinoids and cancer prevention, including skin cancer, the International Agency for Research on Cancer concluded that, despite some agents showing cancer preventive activity in humans, their toxicity was likely to limit their use [76]. Twelve years later this remains the case, with therapeutic use reserved usually for very high-risk patients actively developing large numbers of new skin cancers, such as those with XP, nevoid BCC syndrome, or selected transplant patients [77,78]. A single randomized controlled trial has assessed the efficacy of 25 mg oral acitretin, 5 days a week for 2 years as a skin cancer chemopreventive agent versus placebo treatment in 70 immunocompetent high-risk patients (two or more KCs in the previous 5 years) [79]. There was a nonsignificant 60% reduction in the rate of new primary BCCs and SCCs combined, but the authors reported that the results, while negative, appeared to suggest that acitretin decreased the total number of BCCs and SCCs similarly, though with significantly more mucositis and skin toxicities compared with placebo [79]. There is the possibility, however, given the extensive ongoing research into systemic retinoids, that novel retinoids with improved bioavailability and less toxicity will be developed [78] with the result that in the future they may be added to the clinician's armamentarium for general skin cancer chemoprevention.

#### Topical retinoids

Tretinoin applied topically avoids the systemic side effects of oral retinoids and was evaluated in 1131 US Veterans with two or more previous KCs on the face or ears in the prior 5 years [77]. Patients randomized to topical 0.1% tretinoin or a matching vehicle control for 1.5–5.5 years showed no difference in time to development of new BCC or SCC on the face or ears.

#### Comment

Evidence does not support the use of retinoids to prevent skin cancers in the general patient population.

#### Can other medicines reduce the risk of skin cancer?

A meta-analysis of randomized controlled trials of statins for reducing cardiovascular outcomes was conducted in 2009 to evaluate possible chemopreventive potential against melanoma through anti-inflammatory, immunomodulatory, or antiangiogenesis mechanisms [80]. Based on 16 randomized controlled trials involving 62 568 patients (mean age 60 years, average follow-up 4.7 years), statin use did not significantly affect the risk of melanoma.

The possible preventive effect of aspirin and other nonsteroidal anti-inflammatory drugs on the development of various types of

skin cancer as exploratory outcomes has been studied in two trials. A double-blind placebo-controlled randomized trial across eight US academic medical centers evaluated 200 mg celecoxib, a cyclooxygenase 2 inhibitor, or placebo twice daily for 9 months in 240 patients each with 10–40 AKs at baseline [81]. Numbers of BCCs (relative risk [RR], 0.40; 95% confidence interval [CI], 0.18–0.93;  $P = 0.032$ ) and SCCs (RR, 0.42; 95% CI, 0.19–0.93;  $P = 0.032$ ) were fewer in the celecoxib arm, though incidence of AKs, the primary outcome measure, showed no difference compared with placebo. Serious adverse events were similar in the two arms. In the Women's Health Study, a randomized trial of aspirin and vitamin E enrolled 39 876 US women aged 45 or more. Women were randomized to receive either 100 mg aspirin or aspirin placebo every second day and followed up for an average of 10 years for newly diagnosed invasive cancer at all sites, except for KC [82]. No difference in the incidence of melanoma (RR, 0.97; 95% CI, 0.70–1.36) was seen in the low-dose aspirin compared with the placebo group.

#### Comment

Celecoxib may prevent SCCs and BCCs in patients with sun-damaged skin who have high numbers of AKs, but until further evidence is obtained, limiting exposure to UV will continue to be the most effective way of reducing the risk of melanoma.

#### Implications for practice

Of numerous therapies that have been assessed as possible KC skin cancer or melanoma chemopreventives, including topical sunscreen, tretinoin, retinaldehyde, oral retinol, betacarotene, vitamins, isotretinoin, acitretin, nonsteroidal anti-inflammatory drugs, and statins, only regular use of sunscreen has consistent support as a primary preventive agent for SCC and melanoma in the general population [83]. Investigation of the lifetime health costs and benefits of sunscreen promotion in the primary prevention of skin cancers, including melanoma, has shown that routine sunscreen use by white populations who live in sunny climates is likely to be a highly cost-effective investment for governments and consumers over the long term [84].

#### Key points

- There is good evidence that increased sun exposure increases the risk of skin cancer.
- The relationships between sun exposure and BCC and melanoma risk are complex, and observational studies suggest that mechanisms besides cumulative UV exposure are involved.
- Light-skinned people are at much higher risk for skin cancer than those with darker skin.
- There is good evidence that sunscreens can reduce the risk of SCC and melanoma, but sunscreen use alone is not an effective protection strategy against UV.
- There is good evidence to determine that clinician counseling is effective in changing patient behaviors to reduce the risk of skin cancer, particularly in children, adolescents, and young adults 10–24 years.
- Counseling parents may increase their use of sunscreen for children, but there is little evidence to determine the effects of counseling parents on other protective behaviors (clothing, reducing sun exposure, avoiding sun lamps).
- The benefits of sun-protective measures exceed any potential harm.

## Acknowledgments

We are grateful for the fundamental contribution to this chapter made by Ros Weston, its author in the previous edition.

<sup>2</sup>Department of Dermatology, University of Colorado, Denver Health System, Denver, CO, USA

## Localized disease

### Background

Malignant melanoma (MM) of the skin arises from melanocytes within the epidermis. The tumor can become invasive, penetrate the underlying dermis and subcutaneous fat, and metastasize to distant regions of the body. Rarely, MMs also can arise from other areas of the body, including the retina, meninges, gastrointestinal tract, nasopharyngeal epithelium, and vagina. This chapter is focused on primary cutaneous melanoma.

### Incidence

In 2008, the incidence rate of melanoma worldwide was 1.6% [1]. Specifically, over the past 20 years, the incidence of cutaneous MM of all thickness has increased annually in the Netherlands (4.1%) [2] and the USA (3.1% males, 3.4% in females) [3]. A study in Wales reported a 74% increase in MM over a 3-year period, one of the highest reported increases of MM incidence [4].

While incidence has continued to rise in several countries, reports of mortality from Scotland (1.3 per million per year) [5], Canada (9.8 per 100 000 for males and 8.7 per 100 000 for females) [6], and Australia (8.0 per 100 000 for males and 3.1 per 100 000 for females) [7] suggest that mortality rates may have remained stable or declined in some groups, notably in women. US mortality rates from MM decreased from 2002 to 2006 in men and women younger than 65 years. In contrast, mortality rates have increased for older individuals in the USA (6.6% for men and 0.6% for women) [3, 8]. Reductions in mortality rates may be the result of intensive public education campaigns leading to earlier detection of thinner lesions, with a better prognosis. Early recognition of MM and surgical excision present the best opportunity for cure.

### Risk factors

Several environmental and genetic risk factors confer increased risk for developing melanoma. These risk factors include history of dysplastic nevi [9], increased numbers of common melanocytic nevi [9–11], history of sunburns [10, 12], and family history of melanoma [13, 14]. Genetic risk factors for melanoma include mutations in

*CDKN2A* [15, 16] and *MC1R* [17, 18], which are associated with familial melanoma.

### Diagnosis

Over 95% of patients with MM report a history of change in size, shape, or color. Fewer than 50% of patients describe altered sensation and history of bleeding associated with MM [19, 20]. Various clinical guides have been developed to aid the clinical diagnosis of melanoma. Several diagnostic checklists for melanoma exist, such as the ABCDE rule (A, asymmetry; B, irregular border; C, color variegation; D, diameter  $\geq 6$  mm; and E, evolution) [21, 22] and the seven-point checklist [23]. These diagnostic aids may be useful for identifying potential features of MM; however, their sensitivity and specificity are not well established.

While the main clinical features in MM include irregular pigmentation and shape, significant variations in clinical presentation exist. Dermoscopy can aid diagnosis, but training and experience are required to maximize its usefulness [24]. Newer digital imaging systems have been developed to aid in the diagnosis of pigmented lesions [25].

### Prognosis

The prognosis of localized MM depends on a number of factors, including sex, age, tumor site, and ulceration, but the most significant prognostic factor is the Breslow thickness [26]. This is a measurement of the tumor from the granular layer of the epidermis down to the depth of tumor invasion. In 2010, melanoma staging was modified by the American Joint Committee on Cancer. The changes included the addition of the dermal mitotic rate as a prognostic parameter. Therefore, histologic features that predict survival are (1) Breslow thickness, (2) presence of ulceration, and (3) mitotic rate defined by the number of dermal mitoses per square millimeter [27–29].

With excision, MMs that are less than 1 mm in depth have excellent prognosis with approximately 96% 20-year survival rates [30]. For patients with MM of intermediate thickness (1–4 mm), sentinel lymph node biopsy (SLNB) serves as an important prognostic factor. Positive SLNB predicts a significant reduction in 5-year

survival (72.3% vs 90.2% in SLNB negative) [31]. The involvement of regional lymph nodes with metastases at presentation is associated with survival rates of 25–50% [32]. Tumors deeper than 4 mm are associated with approximately 33–55% survival rates [33]. Prognosis for metastatic MM is discussed in detail in the “Metastatic malignant melanoma” section.

### Treatment objectives

The main aims of surgical treatment are to excise MMs with adequate margins but without creating large postsurgical defects unnecessarily. Various systemic treatments were designed to increase overall survival and progression-free survival, which is defined as the period until recurrence of the primary lesion or distant metastatic spread.

### Methods of search

Medline, PubMed, and Cochrane library databases were searched between the periods January 1966 to June 2012. We retrieved additional relevant literature from the reference lists of the initially identified articles.

### Questions

#### What are the recommendations for surgical excision margins based on the Breslow thickness of the melanoma?

Breslow thickness represents the depth of invasion of cutaneous melanoma from the granular layer. It is the best indicator of prognosis in primary cutaneous MM [26]. Most clinical trials use the Breslow thickness to categorize patient groups. Based on the results of these trials, surgical margins for excision of MM have decreased over the past 20 years.

#### Efficacy

**Melanoma in-situ** No randomized controlled trials (RCTs) have been conducted to determine optimal surgical margins for melanoma in-situ. In 2011, the American Academy of Dermatology published guidelines of care for the management of primary cutaneous melanoma that recommended a 0.5–1 cm margin for surgical excision of melanoma in-situ [27].

**Melanoma with Breslow thickness <2 mm** The World Health Organization Melanoma Group randomized 612 patients with melanomas less than 2 mm in depth to either 1 cm or 3 cm margins from surgical excisions [34]. The 12-year survival rate of patients randomized to the 1 cm margin arm of the study was not statistically significant when compared with those who underwent excision with 3 cm margins (87.2% and 85.1%,  $P = 0.77$ ). Local recurrence rates were also not statistically significant between the 1 and 3 cm margin study arms (2.6% vs 0.1%,  $P$  value not reported) [34].

The Swedish Melanoma Study Group randomized 769 patients with MM with Breslow depth of 0.8–2.0 mm to either 2 or 5 cm resection margins [35]. In comparison with patients randomized to 5 cm margin, those allocated to 2 cm margin experienced no differences in overall survival (hazard ratio [HR], 0.96; 95% confidence interval [CI], 0.75–1.24) or relapse-free survival (HR, 1.02; 95% CI, 0.8–1.30). A similar study comparing 2 cm versus 5 cm excision margins for MM less than 2.1 mm thick concluded that the wider margin of 5 cm had no impact on either the overall or disease-free survival compared with 2 cm margins [36]. The disease-free survival rates at 10 years were 85% for the 2 cm group and 83% for the 5 cm group ( $P = 0.83$ ). The corresponding results for overall sur-

vival rates at 10 years were 87% and 86% ( $P = 0.56$ ) [36]. There were no significant differences in local recurrence rates or overall survival between the 2 or 5 cm margins for MM less than 2 mm thick in any of the trials [35, 36].

**Melanoma with Breslow thickness >2 mm** Few studies investigate optimal surgical margins in melanomas thicker than 2 mm [37–39]. A multicenter RCT compared 2 cm versus 4 cm surgical excision margins in patients with cutaneous melanoma thicker than 2 mm [37]. Overall survival at 5 years was 65% in the 2 cm group (95% CI, 60–69%) compared with 65% (95% CI, 40–70%) in the 4 cm excision group [37]. Wider margins of 4 cm did not result in improvement of disease-free survival or overall survival rates. A retrospective observational study of 278 patients with thick MMs (median thickness 6 mm) suggested that 2 cm margins were adequate for thick primary melanomas [39].

A US multi-institutional study randomized 486 patients with intermediate-thickness MMs (1–4 mm in depth) to either 2 or 4 cm margins [40]. The median follow-up period was 6 years. The local recurrence rates were not significantly different between the two groups, with 0.8% in the 2 cm margin group and 1.7% in the 4 cm group. The overall survival rates over 5 years were not significantly different between the two groups at 79.5% for the 2 cm group and 83.7% for the 4 cm group [40].

A British RCT of surgical margins in cutaneous melanoma compared 1 and 3 cm margins for patients with MM 2 mm or greater in depth [41]. A total of 900 patients were enrolled; 453 had excisions with 1 cm margin, and 447 underwent excisions with 3 cm margin, with a median follow-up of 5 years. Patients randomized to the 1 cm margin had an increased risk of locoregional recurrence compared with those randomized to 3 cm surgical margin (HR, 1.26; 95% CI, 1.00–1.59;  $P = 0.05$ ). Overall survival was similar in the two groups; compared with those who received 3 cm surgical margin, the risk for death for those randomized to the 1 cm surgical margin group was not significantly elevated (HR, 1.07; 95% CI, 0.85–1.36;  $P = 0.6$ ) [41].

#### Drawbacks

Wider excisions of MM are not necessarily associated with improved disease-free survival or overall survival. Excisions with wider margins may be associated with significant morbidity and require extensive skin grafting [40]. The Melanoma Intergroup Trial found that the use of skin grafting could be reduced by 75% if 1 cm surgical margin is employed rather than 3 cm margins [40].

A British multicenter trial comparing 1 and 3 cm margins in patients with MM deeper than 2 mm showed that, although overall survival was similar for both groups, those who had the narrower 1 cm margins were more likely to develop locoregional metastases (HR, 1.26; 95% CI, 1.00–1.59;  $P = 0.05$ ) [41]. These results suggest that narrow margins in patients with melanoma thicker than 2 mm may carry an increased risk of locoregional metastasis.

#### Comment

To date, no controlled trials have examined the effect of varying surgical margins on outcomes in MM with Breslow thickness <0.75 mm or those >4 mm. Melanoma in-situ has nearly no potential for metastatic spread [42]. The current consensus is that it is appropriate to excise melanoma in-situ with a margin of 5 mm to 1 cm of clinically normal skin to obtain a clear histological margin [27].

For MM with less than 2 mm Breslow thickness, the preponderance of evidence shows that there are no significant differences in

local recurrence or survival between those treated with narrower surgical margins and those who underwent more extensive surgical excision. Studies have found that MMs <1 mm in depth can be appropriately treated with surgical margins of 1 cm and that MMs between 1 and 4 mm in depth can be appropriately treated with margins of 2 cm [34–37]. In patients presenting with Breslow thickness 2 mm or greater, surgical excision with 1 cm margins may result in increased locoregional metastases [41]. For thicker tumors greater than 4 mm, one observational study found that 2 cm margins may be sufficient [39].

### How should patients with lentigo maligna or lentigo maligna melanoma be managed?

Lentigo maligna (LM) refers to an atypical melanocytic proliferation entirely confined to the epidermis. LM usually occurs on sun-exposed sites, such as the face and neck, of elderly patients [43]. It represents the early evolutionary, in-situ phase of lentigo maligna melanoma (LMM) [44]. The risk of progression from the precursor phase to dermal invasion and the development of LMM is approximately 5% [45]. The period for the development of LM to LMM varies widely from approximately 10 years to greater than 50 years [46, 47].

Management of patients with LM or LMM can be challenging. Patients with these lesions tend to be elderly, with other comorbidities that may limit extensive surgery. The affected areas can be large and occur within close proximity of critical anatomical structures. Histological changes within the epidermis may occur at some distance from the clinically apparent borders [44]. For these reasons, full surgical excision with suitable margins may be difficult or even impossible in some patients.

### Efficacy

LM and LMM are discussed separately below.

#### Lentigo maligna

**Surgery** There have been no RCTs examining optimal resection margins in patients with LM. Surgical treatment modalities used to treat LM include wide local excision, Mohs micrographic surgery, and staged excision. Owing to subclinical extension, determining adequate surgical margins for LM may be difficult, and the post-surgical defect may be 2–10 times larger than the original lesion [48].

Surgical treatment of LM with a thorough margin assessment may reduce clinical recurrence. One study examining the use of Mohs surgery in 26 patients with LM reported no recurrences after a median follow-up of 58 months [49]. A retrospective follow-up study using a staged excision technique showed long-term disease-free survival of 95% [50]. The 59 subjects were followed up for a median of 54 months. The authors reported that three had local recurrences and none had distant metastases [50]. In a study of 42 cases of LM that were followed for a period of 3.5 years, there was a recurrence rate of 9% (2/22) following surgical excision, compared with 35% (7/20) with other techniques, such as radiotherapy (3/8), curettage and electrodesiccation (2/8), and cryotherapy surgery (2/4) [51].

**Cryotherapy** There have been no RCTs examining efficacy of cryotherapy for the treatment of LM. Recurrence rates in patients with LM treated with cryotherapy range from 6.6 to 15% [52, 53]. In a small study, 3/20 patients with LM (15%) experienced recurrence after treatment with cryotherapy with a follow-up period that

varied from 7 to 80 months [53]. The authors reported no clinical evidence of recurrence after patients were retreated with cryotherapy (14-month follow-up period) [53].

**Radiotherapy** There have been no RCTs assessing the efficacy of radiotherapy for LM. A study of 593 patients showed 88% complete clinical clearance after one treatment by Grenz rays at follow-up (ranged from 2 to 5 years) [54]. One case series of 68 patients treated with conventional fractionated radiation therapy with superficial X-ray reported two recurrences after a 5-year follow-up [55].

**Other treatments** There have been a few case reports on the use of various laser treatments in LM, but the sample sizes were too small to yield definitive conclusions. A report of three patients with LM treated topically with 5-fluorouracil showed a 100% recurrence rate after 22, 24, and 42 months of follow-up [56]. A similar report of four cases of LM treated with topical tretinoin showed no benefit [36]. Several case reports and small series reported the use of topical imiquimod 5% cream in patients with LM [57, 58]. In one study, 28 patients showed no relapse after a year, and another study reported successful treatment of six patients, with a follow-up of 3–18 months.

#### Lentigo maligna melanoma

**Surgery** No RCTs have been conducted assessing comparative efficacy of various surgical approaches in patients with LMM. A retrospective study of 117 patients treated with staged excision showed a mean surgical margin of 10.3 mm for excision of LMM [44]. A case series of 26 patients with LM and 19 patients with LMM were treated using Mohs micrographic surgery [49]. The authors reported a 100% cure rate after 29 months and a 97% cure rate after 58 months. The 5-year survival rate for invasive LMM is 85%, which is the same as that for any other type of melanoma with the same thickness [59].

**Radiotherapy** An uncontrolled follow-up study examined fractionated radiotherapy in 64 patients with LM and 22 with LMM following excision [60]. Among the 64 patients with LM, none showed signs of recurrence after a mean follow-up period of 23 months. Among the 22 patients with LMM who underwent fractionated radiotherapy, there were two recurrences [60].

### Drawbacks

Surgery and other destructive methods including cryosurgery, radiation, and laser, may result in morbidities such as scarring, deformity, and pigmentary changes. Surgical excision is the mainstay of therapy for LM and LMM; however, surgical intervention may result in large defects [48]. Cryotherapy may lead to inadequate destruction of melanocytes extending down hair follicles. There have been reports of recurrences, sometimes amelanotic in type, following cryotherapy [61]. The use of imiquimod has been associated with a brisk inflammatory response, which is reflected clinically by erythema, swelling, and crusting of the skin [62]. The existing studies investigating treatment of imiquimod in LM utilize inadequate follow-up periods to assess long-term cure rates.

### Comment

A survey of dermatologists in the UK revealed wide variations in practice patterns for LM and LMM [63]. After reviewing the current treatments for LM, Mahendran and Newton-Bishop devised an algorithm that advocates surgery as the initial treatment of choice. Mohs surgery may be particularly useful for LM and LMM lesions

with indistinct margins and large size. Because prognosis of LMM is the same as other subtypes of melanoma with the same Breslow thickness, the same surgical margins are to be used based on melanoma studies inclusive of all subtypes. For lesions that are not amenable to surgical resection, other therapies such as cryotherapy or radiotherapy may be considered for LM [63].

There is a lack of data on the rate and duration of progression of LM to LMM. Elderly patients with LM and multiple comorbidities need to be closely monitored. However, the appropriate interval for follow-up is currently unknown. Follow-up intervals of 6–12 months may not be sufficient for detection of invasive LMM [64].

### What is the role of sentinel lymph-node biopsy?

SLNB involves the identification and biopsy of the initial site of lymph-node drainage from the primary cutaneous melanoma. Injecting blue dye and/or radiolabeled colloid into the skin surrounding the primary melanoma identifies the sentinel node [65]. This reliable technique allows the identification of patients with micrometastases affecting the regional lymph nodes in up to 97% of cases [66].

### Efficacy

To date, the largest clinical trial assessing the effect of SLNB on overall survival and prognosis is the Multicenter Selective Lymphadenopathy Trial (MSLT) [67]. From 1994 to 2002, 1269 patients with clinically localized intermediate-thickness (1.43 median thickness) primary melanoma were randomized to either (1) wide excision and SLNB or (2) wide excision and observation. Melanoma-specific 5-year mortality was not significantly different between the SLNB group and the observation group (87.1% vs 86.6%) [31]. However, at 5 years, the distant disease-free survival was significantly improved in the SLNB group compared with the observation group (78.1% vs 73.1%;  $P = 0.009$ ).

SLNB is considered a reliable indicator of prognosis and was incorporated in the American staging system for MM (the 2002 American Joint Committee on Cancer staging) [68]. Data from MSLT-I revealed prolonged disease-free survival (83.2% vs 53.4%;  $P < 0.001$ ) and lower 5-year mortality (9.7% vs 26.2%) in those with negative SLNB compared with those with a positive SLNB. In patients with negative SLNB results, the rates of nodal recurrence ranged from 3.4 to 4.1% after median follow-up of 35–58.9 months [31, 69].

Gershenwald *et al.* demonstrated that, in the 580 patients with median MM thickness of 1.80 mm, 15% of patients were found to have lymph node involvement of MM upon SLNB [70]. This study showed that sentinel-node status was the most significant prognostic factor in predicting disease-free survival. While tumor thickness and ulceration predicted survival in sentinel-node-negative patients, they provided no additional prognostic information in sentinel-node-positive patients [70].

The psychological benefits of obtaining accurate staging for patients have not been studied extensively. One questionnaire-based study involving 110 patients showed increased reassurance and satisfaction in those who underwent SLNB, regardless of the result of the biopsy [71].

### Drawbacks

A meta-analysis reviewed complications in 437 sentinel node biopsies in 269 patients with MM from 1994 to 2009 [72]. Following SLNB, the reported complication rate was 4.26%. Observed complications include wound infection (1.83%), seroma (0.61%), and postoperative pain (0.61%) [72]. When SLNB is followed by com-

plete lymph-node dissection, nearly a quarter of patients experience major or minor complications from the procedure [73].

### Comment

To date, no study has shown a survival benefit in patients who underwent SLNB. However, SLNB is generally accepted as a useful staging procedure in patients with primary cutaneous melanoma without clinically evident lymph node involvement. It is appropriate for patients with melanoma thickness between 1 and 4 mm or melanoma thickness  $\leq 1$  mm associated with high-risk features for metastasis (i.e., evidence of ulceration, mitotic rate  $\geq 1/\text{mm}^2$ , or lymphatic or vascular invasion). The utility of SLNB is controversial in tumors with Breslow's thickness  $> 4$  mm. However, conducting SLNB in patients with melanoma thickness  $> 4$  mm may be of prognostic benefit and help guide treatment strategies [74].

### Are there any effective adjuvant treatments for malignant melanoma following resection?

Several studies elucidating the mechanism of action of interferon- $\alpha$  (IFN $\alpha$ ) propose that IFN $\alpha$  may have immunomodulatory or antiproliferative effects on MM [75]. Some studies support the role of indirect immunomodulatory mechanisms rather than direct antitumor mechanisms (i.e., apoptosis, anti-angiogenesis, cytotoxic effects) [76]. One study suggested that a possible reduction in regulatory T cells results in increased antitumor activity [75].

The role of IFN $\alpha$  in the treatment of melanoma is limited to adjuvant therapy following resection of high-risk stage II or III melanoma. The different subtypes of IFN $\alpha$  investigated in the melanoma literature are interferon  $\alpha$ -2a (IFN $\alpha$ 2a), interferon  $\alpha$ -2b (IFN $\alpha$ 2b), and pegylated IFN $\alpha$ 2a and IFN $\alpha$ 2b. The advantage of the pegylated form of IFN $\alpha$  is the extended half-life and reduction of dosing interval.

### Efficacy

The benefit of IFN $\alpha$  as an adjuvant therapy for high-risk melanoma has been demonstrated in several clinical trials [77]; however, the optimal dose and scheduling intervals have yet to be clearly established. High-dose IFN $\alpha$  regimens usually consist of 20 million IU/m<sup>2</sup> intravenously 5 days/week for 4 weeks followed by 1 million IU/m<sup>2</sup> subcutaneously for 11 months. While high-dose regimens have demonstrated the greatest benefit, intermediate- and low-dose therapies have been investigated to assess efficacy and adverse effect profile. The dose for intermediate IFN $\alpha$  varies between 10 million IU five times/week for 4 weeks, then either 10 million IU three times/week for 1 year or 5 million IU three times/week for 2 years [78]. Other intermediate-dose regimens include pegylated IFN $\alpha$ 2b 6  $\mu\text{g/kg}$  per week for 8 weeks, then 3  $\mu\text{g/kg}$  per week for 5 years [79]. Low-dose IFN $\alpha$  typically consists of 3 million IU subcutaneously for 3 days/week for 18 months.

**High-dose interferon** An RCT of 287 patients with MM greater than 4 mm thickness showed significant improvement in disease-free and overall survival in those treated with high-dose IFN $\alpha$ 2b treatment (intravenous 20 million IU/m<sup>2</sup> 5 days/week for 1 month, then subcutaneous 10 million IU/m<sup>2</sup> three times/week for 11 months) compared with surgery alone [77]. After 7 years of follow-up, the median relapse-free time in the high-dose IFN $\alpha$ 2b group was 1.70 years, compared with 0.98 years in those treated with surgery alone ( $P = 0.002$ ). The median survival time in the high-dose IFN $\alpha$ 2b group was 3.8 years, compared with 2.8 years in those treated with surgery alone ( $P = 0.002$ ) [77].

A large three-arm study of 642 patients showed no statistically significant differences in the overall survival of patients treated with either (1) high-dose IFN $\alpha$  for 1 year (20 million IU/m<sup>2</sup> per day for 5 days/week for 4 weeks and then 10 million IU/m<sup>2</sup> subcutaneously 3 days/week for 48 weeks), or (2) low-dose IFN $\alpha$  for 2 years (3 million IU/day 3 days/week), or (3) compared with no therapy [80]. An observational study from the same authors compared high-dose IFN $\alpha$ 2b with vaccine treatment (GM2-KLH/QS-21) in patients with resected stage IIB–III melanoma of the skin [81]. A total of 880 patients were randomized to high-dose IFN $\alpha$ 2b (intravenous 20 million IU/m<sup>2</sup> per day for 5 days/week for 4 weeks and then 10 million IU/m<sup>2</sup> subcutaneously TIW for 48 weeks) and vaccine. Compared with those receiving the vaccine, patients receiving IFN $\alpha$ 2b had significantly improved relapse-free survival (HR, 1.47; 95% CI, 1.14–1.90;  $P = 0.0015$ ) and overall survival (HR, 1.52; 95% CI, 1.07–2.15;  $P = 0.009$ ) [81].

**Intermediate-dose interferon** In an RCT, 1388 patients with thick primary melanomas (>4 mm depth) or regional lymph-node involvement were randomized to receive IFN $\alpha$ 2b for either 13 months or 25 months or observation [78]. The treatment regimen was 4 weeks of 10 million units of subcutaneous IFN $\alpha$ 2b followed by either 10 million IU of IFN $\alpha$ 2b 3 days/week for a year or 5 million IU 3 days/week for 2 years. After a median follow-up of 4.65 years, those randomized to the IFN $\alpha$ 2b treatments did not have significantly improved distant metastasis-free survival or overall survival compared with observation alone. Therefore, in this subset of patients, the authors could not recommend the use of intermediate-dose IFN $\alpha$ 2b [78].

Another study investigating intermediate-dose adjuvant therapy consisted of 855 patients with stage IIB–IIC or III melanoma [82]. Patients were randomized to (1) IFN $\alpha$ 2b 10 million IU dose subcutaneously 5 days/week for 4 weeks followed by IFN $\alpha$ 2b 10 million IU dose subcutaneously 3 days/week for 12 months; or (2) IFN $\alpha$ 2b 10 million IU dose subcutaneously 5 days/week for 4 weeks followed by IFN $\alpha$ 2b 10 million units flat dose subcutaneously 3 days/week for 24 months; or (3) observation only. The authors reported no significant improvement of overall median survival in patients treated with IFN $\alpha$ 2b compared with observation (56.1 months, 72.1 months, and 64.3 months, respectively;  $P = 0.60$ ) [82].

**Low-dose interferon** Several clinical trials have used low-dose subcutaneous IFN $\alpha$  (3 million IU three times weekly) in patients presenting with MMs greater than 1.5 mm thick but with negative lymph nodes [83–85]. In one trial of 499 patients, relapse-free survival and overall survival were compared in patients treated with low-dose IFN $\alpha$ 2a for 18 months and no treatment [83]. There was a significant 25% extension of the relapse-free survival time from 1.3 to 2.1 years ( $P = 0.03$ ). The 5-year relapse rates were 43% for the IFN $\alpha$ 2a group and 51% for the control group. The 5-year death rates were 24% in the IFN $\alpha$ 2a group and 32% in the control group [83].

Another low-dose trial randomized 311 patients to receive IFN $\alpha$ 2a (3 million IU subcutaneously daily for 3 weeks followed by 3 million IU subcutaneously 3 days/week for 12 months) versus observation after surgical removal of the melanoma [84]. At approximately 41 months, 24% of those treated with IFN $\alpha$ 2a developed metastases compared with 36% of the observation arm ( $P = 0.02$ ). The statistically nonsignificant difference in mortality rate was 11% in the IFN $\alpha$ 2a compared with 13% in the observation arm ( $P$  value not reported) [84].

A randomized controlled study examined overall survival and disease-free survival in 674 patients with MM greater than 4 mm in depth or with locoregional metastases [86]. These patients were randomized to either (1) low-dose treatment with IFN $\alpha$ 2a (3 million IU 3 days/week for 2 years or until recurrence) or (2) no adjuvant treatment. There were no differences in the overall survival ( $P = 0.6$ ) or disease-free survival ( $P = 0.3$ ) [86].

### Drawbacks

Adverse effects significantly limit the use of high-dose IFN $\alpha$ . Toxicity and withdrawal from therapy are frequently reported in the high-dose IFN $\alpha$  studies [87]. Treatment-related deaths have been reported [55]. Ten percent of patients treated with high-dose IFN $\alpha$  discontinued treatment because of adverse events [57]. The most frequent adverse effects associated with high-dose IFN $\alpha$ 2b include 10% of people experienced significant toxicity as well as mild symptoms such as nausea and flu-like symptoms [88].

Patients on IFN $\alpha$  therapy may develop autoimmune-like diseases, including the development of autoantibodies, thyroid dysfunction, and vitiligo [89, 90]. However, the development of autoimmunity may correlate with improved prognosis [89].

### Comments

While adjuvant therapy with IFN $\alpha$  may not confer a significant benefit on overall survival, high-dose IFN $\alpha$  appears to improve relapse-free survival significantly. A comprehensive meta-analysis of the data on adjuvant treatment with IFN $\alpha$  has demonstrated a dose-dependent effect on recurrence-free survival and a statistically nonsignificant effect of benefit for overall survival [64].

### Key points: localized disease

- The incidence of cutaneous MM continues to rise worldwide.
- The main treatment for primary cutaneous melanoma is surgical excision.
- The recommended surgical margin for excision of melanoma in-situ is between 5 and 1 mm.
- MM 1–4 mm of depth can be appropriately treated with surgical margins of 1 cm and MM >4 mm in depth with 2 cm margins.
- Data are lacking on effective treatments for LM and LMM.
- SLNB is a useful staging tool, but it does not appear to improve overall survival.
- High-dose IFN $\alpha$ , used as adjuvant treatment, improves disease-free survival, but its benefit in overall survival is marginal. Dose-dependent adverse effects limit the use of IFN $\alpha$ .

### Metastatic malignant melanoma

Metastatic MM (stage IV melanoma) is defined by dissemination of the cutaneous tumor to other organs or nonregional lymph nodes. The most common initial sites of metastasis are the skin, subcutaneous tissues, and lymph nodes in 59% of patients [91]. When MM metastasizes to distant organs hematogenously, it is among the most aggressive malignancies and carries poor prognosis. The skin (38%), lung (36%), liver (20%), and brain (20%) are the most common sites for distant metastasis of cutaneous melanoma [91].

**Table 31.1** Comparison of single-agent dacarbazine with the Dartmouth regimen of combination chemotherapy.

	Dacarbazine	Dartmouth regimen
Response rate (%)	9.9	16.8
Median survival in months (95% CI)	7.7 (5.4–8.7)	6.3 (5.4–8.7)
1-year survival (%)	27	22

The median survival time for patients with metastatic disease (stage IV) is approximately 7 months; the estimated 5-year survival rate is 6% [92]. Predictors of decreased survival include poor performance status, increasing number of organ involvement, liver involvement, and non-liver visceral involvement (Table 31.1) [93]. Elevated serum markers, LDH and S100B, are also negative prognostic factors for patients with distant metastasis [94].

**Questions**

**What therapies improve overall survival in patients with metastatic malignant melanoma?**

The US Food and Drug Administration (FDA) approved high-dose interleukin-2 (IL-2) for the treatment of metastatic melanoma in 1998. IL-2 is an immunomodulatory agent that may function by stimulating T cell populations to elicit an antitumor immune response [95]. Of the patients who respond to IL-2, approximately 7% achieve complete response and remission for up to 8 years [96]. Use of IL-2 therapy is limited by severe toxicity (see Drawbacks section).

In 2011, the FDA approved ipilimumab and vemurafenib for the treatment of metastatic melanoma. Immunotherapies that target cytotoxic T-lymphocyte antigen-4 (ipilimumab) or inhibit the MAP kinase pathway (vemurafenib) have both shown significant improvement of overall survival in patients with disseminated disease [97–99].

**Efficacy**

**High-dose interleukin-2** The recommended dose for high-dose IL-2 is intravenous 600 000–720 000 IU/kg every 8 h for a maximum of 14 doses. One study treated 134 patients with metastatic melanoma with 720 000 IU/kg intravenously every 8 h for a maximum of 15 doses per cycle (total two cycles) [96]. Seven percent of patients with metastatic melanoma achieved complete regression and 14 patients (10%) had partial regression after treatment with high-dose IL-2 after 28 months follow-up.

A phase III study involving 185 patients with advanced stage III or stage IV cutaneous MM compared (1) IL-2 alone (720 000 IU/kg of body weight per dose) versus (2) gp100:209-217(210M) plus incomplete Freund’s adjuvant (Montanide ISA-51) once per cycle, followed by IL-2 [100]. Compared with those randomized to the IL-2-only arm, those receiving combined vaccine and IL-2 arm showed significant improvement in the overall clinical response (16% vs 6%,  $P = 0.03$ ), as well as increased progression-free survival (2.2 months, 95% CI, 1.7–3.9 vs 1.6 months, 95% CI, 1.5–1.8;  $P = 0.008$ ). Additionally, the median overall survival time was increased in the combined vaccine and IL-2 arm compared with in the IL-2-only arm (17.8 months, 95% CI, 11.9–25.8 vs 11.1 months, 95% CI, 8.7–16.3;  $P = 0.06$ ) [100].

**Ipilimumab** Ipilimumab is a human monoclonal antibody that binds cytotoxic T-lymphocyte antigen-4 to decrease tumor tolerance via upregulation of antitumor T-cell responses. In phase III trials, improvement in overall survival was seen in patients treated with ipilimumab when used as monotherapy (compared with glycoprotein 100 (gp100) vaccine) or when used in conjunction with dacarbazine (dimethyltriazenoimidazole carboxamide) compared with placebo combined with dacarbazine [97, 98]. In one study, 676 patients with previously treated unresectable metastatic melanoma were randomized to (1) ipilimumab (3 mg/kg of body weight) with gp100 vaccine, (2) ipilimumab alone, or (3) gp100 alone once every 3 weeks for four treatments [97]. The authors reported a significant increase of approximately 4 months in overall survival among patients receiving ipilimumab plus gp100 compared with patients receiving gp100 alone (10.0 vs 6.4 months;  $P < 0.001$ ) [97].

Another study in previously untreated patients with metastatic melanoma showed significantly increased overall survival in patients receiving ipilimumab (10 mg/kg every 3 weeks for four doses) and dacarbazine (850 mg/m<sup>2</sup> every 3 weeks for up to 22 weeks) compared with those who received placebo and dacarbazine (47% vs 36% at 1 year follow up;  $P < 0.001$ ) [98].

**Vemurafenib** Vemurafenib, a selective inhibitor of *BRAF* mutations, showed similar efficacy in patients with metastatic melanoma. A phase III study that enrolled 675 patients with MM containing V600E mutation in *BRAF* compared vemurafenib with dacarbazine in patients with unresectable stage IIIC or metastatic disease. The interim analysis revealed lower mortality (HR, 0.37; 95% CI, 0.26–0.55) and lower tumor progression (HR, 0.26; 95% CI, 0.20–0.33) in those treated with vemurafenib compared with dacarbazine [99].

**Drawbacks**

The choice of appropriate immunotherapy varies depending on MM characteristics and patients’ baseline comorbidities. Potential adverse events due to IL-2 include nausea, diarrhea, hypotension, and hepatic and renal dysfunction [96].

Risks associated with ipilimumab therapy include severe immune-mediated reactions (i.e., hepatitis, enterocolitis, endocrinopathies), and therefore ipilimumab should be avoided in patients with autoimmune diseases or organ dysfunction [97, 101]. Transient exacerbation of disease, manifesting as new MMs or progression of pre-existing MMs, may be observed in approximately 10% of patients on ipilimumab prior to achieving therapeutic response [102].

Vemurafenib is indicated only in patients with melanomas with a V600E mutation in *BRAF*. Eruptive keratoacanthomas and squamous cell carcinoma are reported during initial weeks of therapy with *BRAF* inhibition due to paradoxical activation of MAP kinase pathway [99, 103].

**Comments**

The advent of novel immunotherapies has ushered a greater number of treatment options for patients with metastatic MM. Therapy with IL-2 may result in complete remission for <11% of metastatic melanoma patients [104]; however, the toxicity of this treatment limits its use to healthier individuals without end organ damage. Treatments with ipilimumab and vemurafenib have shown improved progression-free survival and overall survival. Owing to the potential for severe immune-mediated adverse effects, ipilimumab is most appropriate for patients without history of autoimmune

disease and organ dysfunction. The use of vemurafenib is limited to melanomas that harbor the V600E mutation in *BRAF*.

### Which chemotherapeutic agents are effective in treating metastatic melanoma? Are combination therapies effective?

#### *Efficacy*

Dacarbazine is an FDA-approved chemotherapeutic agent for the treatment of metastatic melanoma. Dacarbazine is an alkylating agent which functions by inducing DNA strand breakage and apoptosis. Historically, dacarbazine is considered to be the standard treatment against which newer therapies are evaluated [105]. When used as monotherapy for metastatic melanoma, dacarbazine results in partial response (>50% regression for at least 4 weeks) rates of about 20%, complete responses (total regression of measurable disease for at least 4 weeks) in 3–5%, and long-term remissions in fewer than 2% of patients [106]. It is usually given intravenously at 850–1000 mg/m<sup>2</sup> on day 1 every 3 weeks [98, 107, 108] or 200 mg/m<sup>2</sup> on days 1–5 every 4 weeks [109, 110].

Temozolomide is an oral alkylating agent with a broad spectrum of antitumor activity. It has 100% oral bioavailability and good penetration of the blood–brain barrier and cerebrospinal fluid. Temozolomide has been studied off-label for the treatment of MM. The most commonly administered dose in clinical trials is 150–200 mg/m<sup>2</sup> for 5 days every 4 weeks [111, 112]. Its efficacy is at least equal to that of dacarbazine in metastatic MM [111]. Specifically, the median overall survival for temozolomide is 7.7 months compared with 6.4 months with dacarbazine (HR, 1.18; 95% CI, 0.92–1.52) [111].

#### *Drawbacks*

The dose-limiting toxicities with chemotherapeutic regimens such as dacarbazine and temozolomide are bone-marrow suppression and nausea/vomiting, requiring hospital admission or threatening life in 20% and 5% of patients, respectively [113, 114]. To reduce nausea and vomiting, anti-emetic therapy may be administered prior to treatment.

#### *Comments*

Prior to the approval of immunotherapeutic agents ipilimumab and vemurafenib, dacarbazine was the mainstay of therapy for metastatic melanoma. Dacarbazine has been used as a single agent or in combination therapies with other chemotherapy regimens or immunotherapies (see Combination therapy). In clinical studies, dacarbazine monotherapy showed response rates of 5–25% [115]. The combination of dacarbazine with other chemotherapeutic and chemohormonal agents offers no additional survival benefit than dacarbazine alone [113, 116–118].

Another alkylating agent, temozolomide, has shown equal efficacy to dacarbazine [111]. Temozolomide may penetrate the blood–brain barrier and may have some efficacy in central nervous system metastasis [119].

### Does combination chemotherapy help?

#### *Efficacy*

Many other drugs – such as platinum agents, vinca alkaloids, nitrosoureas, and taxanes – have been tried alone and in various combination regimens. It remains unclear whether certain combination therapies offer significant survival advantage over single-agent therapy with dacarbazine. In one study, a response rate of 55% was reported for the combination of dacarbazine, cisplatin, carmustine,

and tamoxifen (Dartmouth regimen) [120]. However, in a multicenter RCT comparing the Dartmouth regimen with single-agent dacarbazine, the investigators found no significant survival advantage and only a small, nonsignificant increase in tumor response (Table 31.1) [113].

Hormonal therapy using tamoxifen, an estrogen receptor-blocking agent widely used to treat breast cancer, has been used in combination with cytotoxic agents to modify the tumor response. One study in 117 patients showed greater efficacy of combining tamoxifen with dacarbazine compared with dacarbazine alone (response rates 28% vs 12%, respectively,  $P = 0.03$ ; median survival 48 weeks vs 29 weeks,  $P = 0.02$ ) [121]. Unfortunately, these results were not replicated in a four-arm RCT involving 258 patients with metastatic MM comparing (1) dacarbazine alone, (2) dacarbazine plus IFN $\alpha$ , (3) dacarbazine plus tamoxifen, or (4) dacarbazine plus IFN $\alpha$  and tamoxifen. Response rates were 19% (95% CI, 12–26) for patients receiving tamoxifen and 18% in the non-tamoxifen group (95% CI, 12–25) [114].

Whether the antitumor responses from existing systemic therapy can be boosted by the addition of immunotherapy is an area of active investigation [122, 123]. One meta-analysis compared (1) dacarbazine-containing treatments, (2) non-dacarbazine-containing regimens, and (3) chemotherapy combined with immunotherapy in metastatic MM [123]. The meta-analysis included 12 RCTs with a total of 3273 patients. The addition of IFN $\alpha$  to dacarbazine increased the response rate by 53% over dacarbazine alone (95% CI, 1.10–2.13). Dacarbazine-containing combination therapy was associated with a better response rate when compared with dacarbazine monotherapy (odds ratio, 1.23; 95% CI, 1.02–1.48). Despite the modest increase in response rates, there was no overall survival advantage for combination treatment compared with dacarbazine monotherapy.

#### *Drawbacks*

Bone-marrow suppression, nausea, vomiting, and fatigue were significantly more common with the Dartmouth combined therapy than dacarbazine alone [113]. Common adverse events during tamoxifen therapy include hot flushes, vaginal dryness, and sleep disturbances. Serious adverse events such as thromboembolic events, pulmonary embolism, and endometrial cancer may occur as a result of tamoxifen therapy [124].

Interferons commonly cause malaise, fevers, and flu-like symptoms. High-dose IFN $\alpha$  caused significant (greater than grade 3) myelosuppression, hepatotoxicity, and neurotoxicity in 24%, 15%, and 28% of the patients, respectively [77]. With low-dose IFN $\alpha$ , 10% of people experienced serious adverse events [88].

#### *Comment*

The evidence to date is insufficient to support the use of combination chemotherapy using dacarbazine with the addition of cytotoxic chemotherapy (i.e., vinblastine, cisplatin, paclitaxel) or hormonal therapy (i.e., tamoxifen) as first-line therapy for metastatic melanoma.

### Does antisense therapy against B-cell lymphoma 2 improve outcomes in patients with metastatic melanoma?

#### *Efficacy*

Oblimersen is an antisense molecule that targets B-cell lymphoma 2 (Bcl-2); it is a key inhibitor of the mitochondrial apoptosis signaling pathway. In a randomized trial, 771 patients were randomized to receive single-agent dacarbazine 1000 mg/m<sup>2</sup> every 3 weeks with

or without oblimersen 7 mg/kg per day for 5 days every cycle [125]. The response rates were higher in patients receiving combination of dacarbazine with oblimersen (12.4% vs 6.8%;  $P = 0.007$ ), and there was a trend towards improved median survival (9 vs 7.8 months;  $P = 0.077$ ).

### Drawbacks

Bcl-2-targeted therapy is associated with neutropenia, thrombocytopenia, fevers, and an increased risk of thrombosis.

### Comment

Antisense treatment targeting Bcl-2 represents a novel treatment modality and shows promise in early clinical trials. More studies are necessary to fully determine its efficacy and safety profile.

### Clinical implications

Developments in the systemic treatment of melanoma have resulted in improved survival for advance metastatic melanoma (Stage IV). Following the approval of ipilimumab and vemurafenib, dacarbazine is no longer the gold standard of therapy for metastatic melanoma. Studies demonstrate both ipilimumab and vemurafenib significantly increase overall survival in patients with metastatic melanoma [97, 98]. Immunotherapy with IL-2 is associated with the potential of complete remission; however, its use is limited by severe toxicity. The role of cytotoxic chemotherapeutic agents, as monotherapy and in combination regimens, is limited in initial treatment for metastatic melanoma.

#### Key points: metastatic melanoma

- The 5-year survival for patients with metastatic melanoma is 5%.
- Treatment with IL-2 may result in complete remission in 7% of patients after 28 months of follow-up. IL-2 treatment may be associated with severe toxicity, such as hypotension, pulmonary edema, arrhythmia, and rarely death. Its use in patients with organ impairments must be carefully monitored.
- Targeted immunotherapy with ipilimumab and vemurafenib results in significantly prolonged survival benefits and progression-free periods in patients with metastatic melanoma.
- Ipilimumab therapy may result in severe immune-mediated adverse effects, such as endocrinopathy and colitis.
- Vemurafenib is strongly recommended for patients with metastatic melanoma with V600 mutation in *BRAF*.
- Treatment with vemurafenib may result in eruptive keratoacanthomas and squamous cell carcinomas.

<sup>2</sup>Department of Dermatology, Circle NHS Treatment Centre, Nottingham, UK

## Background

### Definition

Squamous cell carcinoma (SCC) of the skin, the second most common type of nonmelanoma skin cancer (NMSC), is a malignant tumor arising from keratinocytes in the epidermis (Figure 32.1). Invasive SCC is defined as the passage of atypical keratinocytes through the basement membrane into the dermis and is thus distinguished from potential SCC precursor conditions on an architectural rather than histological basis.

Invasive SCC has the propensity to cause local tissue destruction and may also metastasize to regional lymph nodes or distant organs, occasionally causing death.

The focus of this chapter is nonmetastatic invasive cutaneous SCC. Prevention of SCC is discussed in Chapter 30. Excluded from this chapter are precursor lesions, SCCs of mucosal surfaces (head and neck, lung, gastrointestinal tract, urogenital tract), and SCC of the penis, vulva, and anus.

### Incidence

NMSCs are the most common malignancies in Caucasians, with an approximate ratio in the general population of one SCC to every four basal cell carcinomas (BCCs). Lack of standardization of data collection and incomplete registration of NMSCs confound accurate comparisons of incidence in different regions. However, overall, the incidence of SCC has been increasing around the world since the 1960s [1], although some studies suggest that incidence rates of SCC in some areas may now be stabilizing in subgroups of the population [2–6].

Worldwide, the greatest SCC burden is seen in Australia, where population-based epidemiological surveys suggest age-standardized incidence rates of more than 1000 cases per 100 000 per population per year [7–9]. In the USA, incidence rates are in the range 32–155 per 100 000 population for males and 8–29 per 100 000 population for females [10,11]; although far less than those seen in Australia, these are generally higher than age-standardized rates seen across northern Europe, where recorded incidence rates range from 11–46 per 100 000 per population for males and from 5–23 per 100 000

for females [4,5,12–14]. Variations in incidence are also seen within countries and almost certainly reflect differences in ultraviolet (UV) radiation exposure at different altitudes or the distribution of susceptible ethnic groups within the country [1].

Organ transplant recipients have a 65–253 times greater risk of developing SCC than the general population, with reversal of the usual BCC:SCC ratio [15–18]. In Europe, 10- and 20-year post-transplant cumulative incidences of SCC of 7% and 20% respectively have been reported [19], although corresponding incidences in the Australian organ transplant population are considerably greater, at 52% and 82% respectively [18].

### Etiology

Cutaneous SCC may develop *de novo* in apparently healthy skin, within chronic wounds, scars, burns, ulcers, and sinus tracts, or from the pre-existing lesions listed:

- actinic keratosis (solar keratosis)
- Bowen's disease (intraepidermal SCC)
- arsenical keratosis
- erythroplasia of Queyrat
- Bowenoid papulosis of the genitalia
- actinic cheilitis (leucokeratosis of the lips)
- post-irradiation keratosis
- tar keratosis.

The risk of developing SCC depends on the interrelationship between extrinsic factors and the individual's response to these. Those of advanced age, with red or blond hair, and having a propensity to sunburn rather than tan are at increased risk of developing SCC [20], as are albinos and those with genetic conditions such as xeroderma pigmentosum, in which the capacity to repair UV-induced DNA damage is impaired [10]. Cumulative lifetime exposure to UV radiation, particularly UVB (280–315 nm) from sunlight, is a major factor in the development of SCC [21]. The protective effect of skin pigmentation is reflected in the relatively low incidence of NMSC seen in people with skin types V and VI [22–24]. However, the mortality in this group has been shown to be disproportionately high in comparison with incidence [25]. Whereas the sun-exposed skin of the head and neck is the most

**Figure 32.1** A biopsy-proven neurotropic SCC of the temple.

common site for the occurrence of SCC in fair-skinned populations, non-sun-exposed sites are more frequently involved in those with pigmented skin, suggesting that sunlight exposure is a less important etiological factor in this group. The presence of chronic scarring processes and areas of chronic inflammation are the most important risk factors in skin types V and VI [26,27], and SCCs associated with these predisposing factors tend to be more aggressive, with a 20–40% risk of metastasis compared with a rate of 1–2% in sun-induced SCC [27,28].

In addition to direct DNA damage resulting from the creation of pyrimidine dimers by UV light, mutations in the *ras* oncogene and the p53 tumor-suppressor gene have also been strongly implicated in the development of SCC [29–32]. The role of UVA (315–400 nm) in carcinogenesis is less well understood but of importance, with a positive association between sunbed use and SCC risk having been shown in a systematic review [33]. Although UVA appears to be less mutagenic than UVB and is less efficient at producing cyclobutane pyrimidine dimers and pyrimidine–pyrimidine photoproducts, most UVA damage appears to be indirect through formation of reactive oxygen species and the transfer of energy to DNA via mutagenic oxidative intermediates [34].

There is also good evidence that smoking, exposure to arsenic, ionizing radiation, psoralen–UVA (PUVA) therapy, and petroleum by-products can also promote the development of SCC [35–40]. Serological studies are providing evidence of an association between infection with human papillomaviruses and the risk of developing SCC, although the mechanisms of their etiological role remain unclear and further research is required in this area [41–43].

## Prognosis

For the majority of patients with primary SCC the prognosis is excellent. However, cutaneous SCCs have a much greater propensity than most BCCs to metastasize, and when regional or distant metastases do occur, the prognosis is very poor, with a 10-year survival rate of just 20% for those with regional metastasis and less than 10% for distant metastasis [44].

Rowe *et al.* [28] analyzed data from more than 200 studies published from the 1930s to the 1990s, including all reports in which there was treatment of more than 20 patients with SCC, specified separately from BCC, and in which the results were separated by treatment modality. These studies did not have consistent follow-up intervals, and it is doubtful whether the choice of tumor for each modality was similar; however, some features of SCC became clear. The recurrence rate increased as the length of follow-up increased. The overall local recurrence rate after excision of an SCC involving sun-exposed areas was 8%, while the recurrence rates on the ear and lip were 19% and 11%, respectively. The metastatic rate for primary SCC of sun-exposed areas was 5%, while the rates for SCC on the external ear, lip, and areas not exposed to the sun were 9%, 14%, and 38%, respectively. Previously treated recurrent tumors were also associated with a particularly poor prognosis, with an overall metastatic rate of 30%.

The following prognostic features have been correlated with a poorer prognosis for SCCs, and form the basis of the current American Joint Committee on Cancer tumor staging system which can be used in combination with nodal and metastatic status to stratify patients and guide treatment decisions [45]:

- Tumor diameter >2 cm
- Tumor depth >2 mm thick
- Clark's level ≥IV
- Anatomic site ear/lip
- Perineural invasion
- Histological differentiation poor or undifferentiated.

## Diagnostic tests

Diagnosis of cutaneous SCC is by biopsy or excisional biopsy. Invasive SCC is distinguished from SCC in situ by invasion of the dermis by epithelioid cells in atypical nests and cords, and rarely as single cells. Local draining lymph nodes should always be examined for evidence of regional metastasis.

## Aims of treatment and relevant outcomes

The aim of treatment is to remove or destroy the tumor completely and to minimize cosmetic and functional impairment. Success should therefore be measured by rates of recurrence or metastasis at fixed time points, or by survival analyses that document the time to first recurrences in groups of patients. The morbidity of the procedure, as measured by short-term or chronic pain, infection, scarring, skin function, and overall cosmesis, should all be considered when choosing the appropriate treatment modality. In addition, the cost and tolerance of the specific treatment modalities should be considered.

In general, SCC has not been thoroughly or rigorously studied, and there are very few prospective randomized controlled trials (RCTs) [46].

## Methods of search

The following databases were searched up to the end of May 2012:

- The Cochrane Skin Group Specialised Trials Register
- The Cochrane Central Register of Controlled Trials
- The Cochrane Database of Systematic Reviews
- Medline from 1946
- Embase from 1974
- AMED from inception
- PSYCINFO from inception
- LILACS from inception.

Search terms included squamous cell carcinoma, SCC, skin neoplasms, non-melanoma skin cancer, and NMSC. Reference lists and review articles were scrutinized for articles not identified from the database searches.

Owing to lack of relevant RCTs, data from uncontrolled studies have been included in this chapter with comment as appropriate on the limitations of evidence from such sources.

## Questions

The following questions relate to the treatment of a large (>2 cm) invasive SCC with perineural invasion on the temple of a 60-year-old man:

- What are the effective therapeutic interventions for localized invasive SCC of the skin?
- How do the therapeutic interventions for localized SCC of the skin compare with each other?
- How do cosmetic outcomes for these therapeutic interventions compare?

## Evidence summary

### Surgical excision

Surgical excision is still the primary treatment for invasive SCC, usually performed in the outpatient setting under local anesthesia. The standard excision technique involves estimation of the clinically obvious tumor, either visually or via curetting, although there is little evidence that curettage pre-excision of SCCs is of benefit [47]. The surgeon marks an area of normal-appearing skin as an additional margin to be taken around the tumor, the size of which is determined by the prognostic features of the tumor and in accordance with management guidelines [48,49]. After excision the wound is sutured or allowed to heal by secondary intent using appropriate wound-care regimens. The histology of the tumor is examined in formalin-fixed sections, including a sampling of the margins to assess whether the tumor has been completely removed. Examination of the margins is sometimes carried out in frozen sections, which may be immediately available.

### Efficacy

There have been no RCTs which have compared the effectiveness of surgical excision with other treatment modalities. Evidence of effectiveness comes largely from case series with variable follow-up durations, and variable reporting of tumor size and location, so data have to be interpreted with caution. Recurrence rates from such studies range from 0 to 15% [50–67], with SCC of the ear region showing the greatest propensity to recur both locally and regionally. A greater tendency to recurrence has also been noted with large tumors, with Pless reporting local recurrence in 12% (four of 49) of patients with SCC of the pinna less than 1 cm in diameter up to 43% (three of seven) for those whose SCC was greater than 4 cm [59], although six of the 10 patients who developed metastasis in the series by Mourouzis had SCCs smaller than 2 cm in diameter, suggesting that even the smallest SCCs have metastatic potential. Poor differentiation, location on the pinna, and incomplete excision were found to be independent risk factors for regional metastasis in this study [57]. Deaths attributable to SCC are rare after excision of a tumor which is not known to be metastatic at the time of initial treatment, ranging from 0% in two studies of eyelid SCCs [52,61] up to 8% [51,54,55,62–64] for SCCs at various other cutaneous sites.

Recommendations on the width of the margin of normal-looking skin excised around clinically well-defined tumors ranges from 4 mm to 1 cm [48,49], although there have been no RCTs comparing different excision margins for SCC. One study has assessed the margin size required to clear the subclinical extensions in 95% of 141 SCCs using Mohs micrographic surgery (MMS) in incremental stages, and the UK recommendations of 4 mm for “low” risk and 6 mm for “higher” risk SCC are based on this work [68].

### Drawbacks

Large tumors, or tumors in cosmetically complex areas such as near the eyelids or ears, often require a flap or graft for repair. The subsequent scar from surgical excision usually results in a hypopigmented line, and hypertrophic and keloidal changes may occur. Since the surgical site is most often closed at the time of surgery and histology is later evaluated on fixed tissues, the discovery of residual tumor may mean that the patient has to return for further surgical interventions.

### Comment

Surgical excision is still the major definitive treatment option for SCCs.

### Mohs micrographic surgery

MMS, a technique originally devised by Frederic Mohs in 1941 [69], allows precise definition of the extent of the tumor to ensure maximum removal whilst at the same time conserving normal tissue as much as possible. The procedure is carried out in stages over several hours. The surgeon excises the tumor and a small clinically normal-looking margin, processes the specimen as a frozen section, reads the slides to mark margins with residual tumor, re-excises tissue at the positive margin, and processes the new specimen. These steps are followed until all margins are clear of tumor. This differs from excision with frozen section margin control in four ways. First, the initial specimen is excised as one intact disk with beveled edges, yielding a saucer-shaped specimen. This shape facilitates orientation and preparation for microscopic evaluation. Second, the processing of the specimen is different from the processing of specimens as performed by the pathology department. Horizontal sections are prepared in such a way that the entire margin from the epidermis to the deepest portion of the specimen is viewed under the microscope in very few sections. Third, the surgeon is trained to be a histopathologist as well and reads the slides, allowing him or her to orient any residual tumor relative to other structures in the skin, such as the plane of sebaceous glands or a prominent blood vessel.

Final closure is performed once the entire margin is clear. MMS is considered to be a highly curative procedure for NMSCs, since immediate histopathological evaluation of the entire margin is possible. In addition, histopathologically uninvolved skin is spared, as the mapping technique allows specific reexcision of only the involved margins, limiting potential damage to adjacent tissues.

### Efficacy

There have been no RCTs comparing MMS with other treatment modalities for SCC. Using the fixed tissue technique, Mohs reported an overall 5-year cure rate of 97% for the 1894 patients with previously untreated SCCs, and 76% for the 355 patients with SCCs recurrent after prior treatment [70]. Rowe *et al.* [28] analyzed case series up to the 1990s and found a similar 97% 5-year cure rate for primary SCCs treated by MMS, compared with 92% following

standard surgical excision. For previously treated recurrent SCCs, a 90% 5-year cure rate after MMS also compared well with the 77% rate obtained after surgical excision [28]. Evidence from later case series also suggests that recurrences after MMS are fewer than after conventional surgical excision, with local recurrence of between 0 and 5.7% [65,71–79] during follow-up periods that varied between studies ranging from a mean of 18.5 months to 77 months.

### Drawbacks

MMS is expensive and is not accessible to all patients. Full extirpation of the tumor may require multiple stages over a period of many hours. Patients who cannot lie down due to a comorbid condition may not tolerate the potentially lengthy procedure. In addition, the processing of the frozen sections is labor intensive.

### Comment

MMS appears to have lower recurrence rates than conventional surgical excision and radiotherapy. For low-risk small-diameter SCCs (minimally invasive or in low-risk sites), other treatment modalities should be considered, as there is probably little to be gained in efficacy and much to be lost in terms of cost and time.

### Radiotherapy

A wide variety of radioactive modalities and dosages have been used, with irradiation techniques being adapted to tumor characteristics such as location and size. Radiotherapy for SCC generally involves superficial external irradiation of the lesion and its margins. Uninvolved tissue is protected from radiation by the use of specially fitted lead masks or shields as necessary. Several fractionated doses of radiation are delivered over the course of a few weeks; administration of radiation in a single or a few high-dose fractions is now less commonly used, due to the increased risk of radionecrosis.

Brachytherapy, in which the radioactive source is applied directly to the tumor via a surface mold or interstitial wires, is also sometimes used to treat superficial NMSCs, requiring less protracted treatment times than conventional radiotherapy.

Additionally, radiotherapy may be administered to the tumor bed and occasionally to first-echelon lymph nodes as an adjuvant therapy postoperatively with the aim of eradicating residual tumor cells. The most common indications for using radiotherapy like this are histologically incomplete excision and perineural invasion.

### Efficacy

No standard protocols have been tested and generally adopted for radiotherapy for SCC, and no RCTs have examined the effectiveness of radiotherapy in comparison with other treatments for SCC. Several retrospective studies have examined the role of radiotherapy for SCC. Rowe *et al.* [28] analyzed the literature on SCC of the skin from 1940 to 1992 and found an average local recurrence rate of 10.0% after  $\geq 5$  years in 160 patients who had received radiotherapy for primary SCC. Since 1992, further case series have reported local recurrence of between 6 and 13.6% [80–82] for primary SCCs following external radiotherapy, but long-term follow-up data tend to be limited. In the largest series by Barysch *et al.* [82], in which 177 primary SCCs were followed for a mean of 4.9 years, there were 24 recurrences (13.6%), all of which apart from one were located in the head and neck region. The highest 5-year relapse-free survivals in SCCs were located around the eyes (100%) and cheeks (91%). Several case studies in the radiation oncology literature have noted that increasing tumor size is associated with a progressively decreasing success rate in treating SCC with

radiotherapy. Previous treatment is also a poor prognostic factor [83–87].

Several small open-label series have addressed the use of brachytherapy to treat invasive SCCs [88–93]. The largest study with the longest mean follow-up of 45 months reported local recurrence in two patients of 48 (4.2%) [89], and a further study found one local recurrence of 18 SCCs which were followed for more than 12 months [90]. Although the remaining studies reported no recurrences, only a few patients with invasive SCC were included (total 22 patients) and follow-up was generally limited.

A systematic review of the role of surgery plus adjuvant radiotherapy (ART) in high-risk SCCs found that the 91 patients who received ART were at significantly greater risk of developing regional and distant metastases than the 2358 patients who did not [94]. As the studies included did not incorporate data on tumor staging, it is likely that those who received ART had more advanced disease. Clear surgical margins were only recorded in 8% of ART patients, so there was uncertainty about margin status in the majority.

### Drawbacks

Radiotherapy usually requires multiple treatment sessions, which may make it less convenient for patients. Unlike other standard treatments for SCC, ionizing radiation causes a small increased risk of cutaneous carcinoma within the treatment field [95]. Atrophy, hypopigmentation, alopecia, and telangiectases are also commonly seen late cutaneous sequelae of radiotherapy, yielding an eventual suboptimal cosmetic outcome in spite of excellent early cosmesis [96]. These side effects make this modality of treatment for SCC less desirable for younger patients. Given the risk of radionecrosis, caution should also be exercised when considering radiotherapy for lesions overlying bone or cartilage [97].

The main advantages of radiotherapy include preservation of perilesional normal tissue, and the tolerability of the treatment. Radiotherapy does not require anesthesia, and patients who are medically unable to tolerate or who refuse a surgical procedure may be able to undergo radiotherapy. Radiotherapy appears to be an effective treatment for SCC, particularly for small lesions that have not been previously treated. As tumor-free margins are not assessed during treatment, the treatment sites should be closely monitored at follow-up visits for possible recurrences.

Current evidence is insufficient to identify those high-risk features in which ART may be beneficial.

### Electrodesiccation and curettage

Electrodesiccation and curettage (ED&C) is frequently used in the treatment of SCC, particularly for in situ or minimally invasive lesions on the trunk or limbs. Following tumor debulking by curettage, an electric current is applied through a fine-tipped needle in repeated cycles, causing desiccation of the base and destruction of residual tumor.

### Efficacy

There are no RCTs that have compared the efficacy of ED&C with other treatment modalities. Several case series have reported generally excellent cure rates with reported recurrences of between 0 and 4.2% for SCCs treated at various sites [56,66,98–102]. Follow-up periods ranged from less than 1 year up to a mean of 6.8 years. These series include mostly SCCs perceived as being at low risk of recurrence, which may explain the low recurrence. In the series by Knox *et al.*, which had the greatest number of patients treated by

ED&C, there was one case of recurrence of 545 SCCs with 1 year follow-up, with 90% of treated tumors having a diameter of less than 2 cm [56]. Honeycutt and Jansen treated 281 invasive SCCs with ED&C and noted three recurrences (1.1%) during follow up of 4–8 years. Overall, 264 (94%) of the treated SCCs were smaller than 2 cm in diameter, with one recurrence in this group (0.6%) compared with two recurrences in the 17 patients who had SCCs greater than 2 cm in diameter (11.8%) [99].

One small series by Shiffman in which 15 patients with SCC of the pinna (11 with cartilage invasion at the time of diagnosis) were treated with ED&C, reported local recurrence in three (20%) [62]. Two patients died as a result of their disease, one having developed regional and distant metastases, and the other distant metastases. The success of this technique is thus likely to be partly a reflection of the selection of smaller, less-invasive lesions at anatomical sites which are not considered particularly high-risk areas.

### Drawbacks

Cosmetically, the scar from ED&C is usually a hypopigmented sclerotic circle, rather than the thin line resulting from excision. Although the circular scar often contracts, hypertrophic changes can also occur, making it difficult to recognize recurrent SCC. For SCC lesions on the face, particularly adjacent to critical tissues, contraction of resultant scars may distort or destroy the normal or functional anatomy. In addition, a surgeon performing ED&C at sites adjacent to vital or anatomically complex structures (such as the nose or eye) might limit the margins of destruction or be less aggressive in order to preserve native tissue; this is likely to diminish the effectiveness of this technique. Whelan and Deckers [103] found that the majority (65%) of lesions took 4 weeks to heal after ED&C, while in a separate study they found that the average time for healing was 5.1 weeks [104]. Prolonged healing in comparison with surgical excision should be taken into consideration, particularly for lesions on the lower extremities.

With the ED&C technique, no tissue is obtained that can be examined microscopically to determine whether the margins of the treatment are clear of tumor, and there is no information on prognostic factors such as depth of invasion.

### Comment

ED&C appears to be effective for early low-risk SCC lesions and is rapidly and easily performed by the experienced surgical clinician. Adequate follow-up is essential to recognize the rare recurrences.

### Cryotherapy

Cryotherapy involves the delivery of liquid nitrogen to freeze and thaw tissue, resulting in cellular destruction and local inflammation. A rapid freeze and slow thaw maximizes epithelial cell damage and is most suitable for treating skin tumors. Two or three freeze–thaw cycles are generally employed to treat small, low-risk NMSCs, although much variation in practice exists.

### Efficacy

There are no RCTs that have compared the effectiveness of cryotherapy with other treatments. Several case series have reported no recurrences during follow-up ranging from 1 month to 14 years after treatment of selected low-risk SCCs with cryotherapy [105–110]. In a series of 34 low-risk SCCs, Holt reported one SCC that did not respond to cryotherapy, and one recurrence 13 months after treatment of a tumor on the shin [111]. A cure rate of 97.3% was reported by Graham and Clark for 563 new SCCs, with most of the

included SCCs measuring less than 2 cm [112]. Similarly, of 52 new SCCs treated between 1980 and 1984, Kuflik and Gage reported two (3.8%) recurrences of a nose and an ear SCC, an overall 5-year cure rate of 96.1% [113], with a later series by the same authors reporting no recurrences of 134 SCCs treated by cryotherapy between 1990 and 1996 [108]. SCCs which were treated by cryotherapy in these series were generally highly selected for this particular modality, so it is difficult to compare its efficacy with other treatment modalities.

### Drawbacks

Cryotherapy at an effective dosage is always complicated by an initial period of significant edema, followed by formation of a large bulla. After rupture, the wound weeps and then crusts, taking 4–10 weeks to heal. Delayed and temporary adverse events reported after cryotherapy include hemorrhage, infection, milia, hyperpigmentation, and altered sensation. The development of permanent hypopigmentation and occasional hypertrophic scarring may result in an inferior cosmetic outcome compared with other treatments.

With the cryotherapy procedure, no tissue is obtained for histological examination. Since cryotherapy rarely destroys deep tissues, clinically suspected or biopsy-proven invasion into subcutaneous fat or deeper planes should be considered a relative contraindication.

### Comment

Cryotherapy is effective for treating in situ disease and low-risk SCC but is not appropriate for previously treated recurrent tumors or those with high-risk features.

### Photodynamic therapy

Photodynamic therapy (PDT) involves the activation of a topically or systemically delivered photosensitizing agent by light of a specific wavelength in the presence of oxygen. Methyl-aminolevulinic acid (ALA), the photosensitizer currently used in PDT, is preferentially absorbed by neoplastic tissue and converted into photoactive porphyrins. Sufficient time needs to be allowed for accumulation of porphyrins prior to exposure to a light source, usually red or blue light, with a wavelength corresponding to the excitation peaks of the photosensitizer. Cellular dysfunction and death results from the interaction of cellular components with the reactive oxygen species that are generated, resulting in tumor destruction.

### Efficacy

PDT has been shown to be effective for treating actinic keratosis and Bowen's disease [114], although evidence to support its use for treating invasive SCC is much less robust and there have been no RCTs that have included invasive SCCs.

Eleven small open-label studies have described the use of topical PDT to treat invasive SCCs, although there is much variation between them in terms of application time of photosensitizer, light source and dose employed, and total number of treatments [115–125]. Apparent initial complete response rates to topical ALA–PDT in the first few weeks after treatment were highly variable, ranging from 0 to 100%, although there were generally very few invasive SCCs in each study. Residual tumor was found on biopsy in two of 10 treated SCCs that clinically appeared to have responded to PDT [116]. Five of the studies assessed recurrence in those patients whose SCCs had appeared to respond to PDT initially. Whilst there were no recurrences in two of the studies (six patients in total)

during follow-up of 3–38 months [115,124], the remaining studies all reported poor long-term outcomes. Of 16 patients with apparently responsive SCCs, 11 (69%) recurred during 3–47 months follow-up, with an overall predicted disease-free rate of just 8% 36 months posttreatment [118]. An overall response rate (controlled by histology and long-term follow-up of up to 36 months) of 83% was calculated for “superficial” (less than 1 mm thick) SCCs and 33% for “nodular” SCCs [116]. A later study by the same author reported recurrence in six of 14 (43%) responsive invasive SCCs (Clark level II–IV), and in nine of 32 “microinvasive” SCCs (Clark level II) [117].

The use of systemic PDT has been assessed in three open-label trials. Two of the studies reported an initial apparent complete response for all of the 14 included invasive SCCs treated [126,127]. However, residual SCC was found in six of 32 posttreatment biopsies by Pennington *et al.* [128], and with more than 50% of treated SCCs recurring within 6 months after PDT and a lack of correlation between recurrence and the presence of residual tumor at the initial assessment, further recruitment into the trial was abandoned.

### Drawbacks

PDT is not recommended to treat invasive SCCs.

### Comment

There is currently insufficient evidence to support the routine use of topical or systemic PDT to treat invasive SCCs.

### Other treatments

Not all patients are amenable to surgical or radiological treatment, and such treatments may also not be ideal for patients with genodermatoses and immunosuppressed patients who may be afflicted with multiple skin tumors. Such patients have an unmet need for effective topical and systemic therapies, and as new insights into the

pathogenesis of NMSC emerge, the development of targeted therapies is becoming an exciting prospect.

The evidence of the effectiveness of topical and systemic agents that have been used to treat SCC is summarised in Table 32.1.

### Drawbacks

Prolonged treatment duration over weeks to months may render systemically administered regimes inconvenient for patients and decrease patient compliance with topical self-administered therapies. Many unanswered questions remain about optimal doses and the long-term efficacy and safety of these therapies. Not all SCCs express the primary targets (EGFR/VEGR) against which the newer molecular-based therapies are targeted, so may not benefit from such treatments, although identification of molecular markers in future studies may help to screen for those patients who are most likely to respond.

### Comment

Reports of the use of these other treatments is largely limited to case reports of patients with unresectable SCCs, and small numbers of advanced aggressive SCCs in studies which mostly include other types of NMSCs. As experience grows with the use of molecular targeted therapies in noncutaneous SCC, and as trials addressing their use in cutaneous SCCs expand, this is an area where the body of evidence is likely to develop in the future. However, the routine use of these therapies for primary nonmetastatic SCCs is not currently advocated.

### Implications for clinical practice

In considering the clinical scenario of a large perineural SCC on the temple of a middle-aged man, the choice of treatment will largely depend on the geographic medical options for a particular

**Table 32.1** Current evidence for the effectiveness of topical and systemic treatments for cutaneous SCC.

Treatment	Mechanism	Current evidence
Imiquimod (topical)	Immune response modifier	Limited evidence of efficacy for primary invasive SCCs – anecdotal reports in patients unsuitable for surgery [129–137]
5-FU (intralesional/topical)	Pyrimidine analogue	<i>Intralesional</i> 1ml/lesion per week for 6 weeks Multicenter open-label trial 95% clearance at 16 weeks (23 patients). Recurrence not assessed [138] <i>Topical</i> 70% superficial regression in XP patients with multiple facial SCCs ( $n = 10$ ), 80% of those biopsied had residual tumor in deep dermis [139] 79% complete clinical regression of 53 SCCs with no recurrences 1 year posttreatment [140]
Interferon-alpha (intralesional)	Cytokine	Multicenter open-label trial ( $n = 27$ ) 88.9% histological clearance. Recurrence not assessed [141] Retrospective series 61% CR ( $n = 28$ ), 1 recurrence of ear SCC at 4 years [142]
Cetuximab	EGFR inhibitor	Phase II trial 400mg/m <sup>2</sup> , then 250mg/m <sup>2</sup> per week for 6 weeks – 69% disease control at 6 weeks ( $n = 36$ unresectable head and neck cutaneous SCCs) [143] Case report – 400mg/m <sup>2</sup> , then 200mg/m <sup>2</sup> weekly plus $\gamma$ -irradiation for locally advanced inoperable SCC, regressed to surgically operable size by 8 months [144]
Gefitinib	EGFR tyrosine kinase inhibitor	Phase II trial – neoadjuvant gefitinib prior to definitive surgery and/or radiotherapy in 22 aggressive cutaneous SCCs – 45.5% response rate [145]
Erlotinib	EGFR inhibitor	Ongoing phase II trial [146]
Bevacizumab, sorafenib, sunitinib	VEGF inhibitors	No trials with cutaneous SCC, but phase II trials with SCC of the head and neck
Ingenol mebutate ( <i>Euphorbia peplus</i> sap)	Unknown	Phase I/II study 50% CR after mean f/u 15 months [147]

EGFR, epidermal growth factor receptor; VEGF, vascular endothelial growth factor; CR, complete response; XP, xeroderma pigmentosum; f/u, follow-up.

patient, the surgeon's preference, convenience to the patient, and cost. Surgical excision has the advantage of producing a tissue specimen in which the margins can be evaluated histologically using formalin-embedded tissue processing with special stains, and surgical repair would yield a much less obvious scar. ED&C and cryotherapy are inappropriate to treat high-risk SCC. MMS has the advantage that it provides horizontal sections that track the tumor along nerve branches, so that tumor can be cleared before surgical closure. MMS should be considered for this particular lesion because of its aggressive perineural spread seen on biopsy, its proximity to important functional and cosmetic structures in the face, and the technique's ability to achieve and document clear margins before a complex definitive repair.

### Key points

- Risk factors for the recurrence of cutaneous SCCs are the treatment modality, size larger than 2 cm, depth greater than 2 mm, poor histological differentiation, location on the ear or mucosal areas, perineural involvement, location within scars or chronic inflammation, previously failed treatment, and immunosuppression.
- The evidence base for the treatment of cutaneous SCC is poor.
- None of the commonly used procedures has been tested in rigorous RCTs for invasive SCC.
- Case series that have followed up patients with cutaneous SCC treated by surgical excision, MMS, ED&C, cryotherapy, or radiotherapy all suggest 3–5-year recurrence rates of 10% or less. SCCs on the lip and ear recur more commonly.
- Comparison of the recurrence rates between the major commonly used treatments is almost impossible, as the choice of treatment is probably based on the likelihood of success (for example, only people with small uncomplicated SCCs are treated with destructive rather than excisional techniques).
- Small, thin tumors less than 2 cm in diameter in noncritical sites may be treated by surgical excision with 4 mm margins, ED&C, or cryotherapy.
- Higher risk tumors require surgical excision or MMS.
- RCTs with adequate long-term follow-up are needed in order to inform clinicians about the relative merits of the various treatments currently used for people with SCC. Such trials will need to be large in order to exclude small but important differences, and they will need to accurately describe the sorts of people entered in terms of risk factors for recurrences. The follow-up period in such studies needs to be 5 years or longer.

### Acknowledgments

We would like to acknowledge the good work done by Nanette J. Liegeois, Su-Jean Seo, and Suzanne Olbricht, who wrote the chapter for the second edition of *Evidence-Based Dermatology*.

## CHAPTER 33

# Basal cell carcinoma

Fiona Bath-Hextall<sup>1</sup> and William Perkins<sup>2</sup>

<sup>1</sup>Centre of Evidence Based Dermatology, University of Nottingham, Nottingham, UK

<sup>2</sup>Department of Dermatology, Circle NHS Treatment Centre, Nottingham, UK

## Background

### Definition

Basal cell carcinoma (BCC) is defined as a slow-growing, locally invasive malignant epidermal skin tumor, which mainly affects Caucasians [1].

### Incidence/prevalence

BCC (or rodent ulcer) is the most common malignant cutaneous neoplasm found in humans [2,3]. For example, over 30 000 new cases are reported each year in the UK. This is likely to be an underestimate because of inconsistencies in registration of BCCs at regional cancer registries [4]. Many registries only register a person's first skin cancer, thus further underestimating the real burden of the problem (Figures 33.1, 33.2, and 33.3).

The tumor may occur at any age, but the incidence of BCC increases markedly after the age of 40. The incidence of BCC appears to be increasing in younger people, probably as a result of increased sun exposure [5–7]. Cancer registry data from part of the Eastern Region of the UK were analyzed for two periods, 1981–1989 and 1989–2006, and reported incidence of BCC in those <30 years had increased by 145% during the period, corresponding to an average annual increase of 8.53% [8]. A sustained rise in the incidence of BCC has been documented using a validated register in South Wales, UK [3]. In the USA, the incidence of BCC has doubled approximately every 14 years [9], and similar changes have occurred in Australia [10].

### Etiology

Eighty-five percent of all BCCs appear on the head and neck region [11,12]. Risk factors are fair skin, tendency to freckle [13], degree of sun exposure [14–16], excessive sun-bed use, radiotherapy, phototherapy, male sex, and a genetic predisposition [17]. Nevoid BCC syndrome (Gorlin syndrome) is an autosomal-dominantly inherited condition characterized by developmental abnormalities and the occurrence of multiple BCCs. Mutations in patients with nevoid BCC syndrome have been found on the patched gene located on

chromosome 9, which appears to be crucial for proper embryonic development and for tumor suppression [18].

### Clinical patterns

As Figures 33.1, 3.2, and 33.3 show, clinical appearances and morphology for BCC are diverse. They include nodular, cystic, ulcerated (rodent ulcer), superficial, morpheic (scarring), keratotic, and pigmented variants. Nodular BCC is the most common type (60%) in the UK. However, in other countries such as Australia, superficial BCC is the most common type [19]. Eighty-five percent of all BCCs appear on the head and neck region [11,12], visible areas where a good cosmetic and functional result is important.

### Prognosis

Growth of BCC is a localized phenomenon in people with a competent immune system. BCCs tend to infiltrate surrounding tissues in a three-dimensional fashion through the irregular extension of finger-like outgrowths, which may not be apparent clinically [20,21]. If left untreated, or if inadequately treated, the BCC can cause extensive local tissue destruction, particularly on the face. Neglected cases may even infiltrate bone and deeper structures, such as the brain, and cause death [22]. Death from BCC is extremely rare, but may occur in neglected cases and/or those with major underlying immunosuppression. The clinical course of BCC is unpredictable. A BCC can remain small for years with little tendency to grow, it may grow rapidly, or it may proceed by successive spurts of extension of tumor and partial regression [23]. Histological subtype (infiltrative, micronodular, or morpheic patterns), initial diameter, and male sex have been shown to be the best independent predictors of BCC invasion [24]. It is unknown whether the phenotypic characteristics of people who present with clusters of BCCs or those who develop BCCs on truncal sites are also associated with increased growth once a BCC has established.

### Diagnostic tests

The diagnosis is usually made clinically, with histological confirmation being made at the time of the intended definitive treatment –

Figure 33.1 Superficial BCC.

Figure 33.3 A morpheic BCC.

Figure 33.2 A nodular BCC.

### Search methods

The following databases were searched up to the end of April 2012:

- Medline from 1966;
- Embase from 1980;
- The Cochrane Skin Group Specialized Trials Register;
- The Cochrane Library, Cochrane Database of Systematic Reviews, and Cochrane Central Register of Controlled Trials;
- Mega Register of Controlled Trials on the Current Controlled Trials website and the National Research Register's Medical Research Council (MRC) Clinical Trials Directory.

The search strategy used to locate randomized controlled trials (RCTs) included search terms given in the *Cochrane Reviewers' Handbook* [25]. Search terms included: BCC, basal cell carcinoma, basal cell cancer, nodular BCC, nevoid BCC, Gorlin syndrome, rodent ulcer, Jacob's ulcer, basal cell epithelioma, basalioma, and nonmelanoma skin cancer (NMSC), including squamous cell carcinoma and BCC.

Prevention of skin cancer is discussed in Chapter 30.

often surgical removal. Diagnostic biopsies are usually performed before treatments such as radiotherapy.

### Aims of treatment

The three fundamental principles of treatment are to:

- eradicate the tumor;
- preserve function;
- produce an excellent or acceptable cosmetic result.

From a patient's perspective, the treatment should result in as little distress as possible in terms of pain, number of hospital visits, and scarring. From a health provider's perspective, it is important to balance efficacy against cost.

### Relevant outcomes

- Clearance of the lesion, as measured by absence of early treatment failure (within 6 months) and absence of long-term recurrence of the lesion measured at 3–5 years.
- Adverse effects in terms of atrophy, scarring, changes in pigmentation, and discomfort to the patient in terms of pain during treatment and afterwards.

### Questions

- What are the effective therapeutic interventions for BCC of the skin?
- How do the therapeutic interventions for BCC compare with each other?
- How do the cosmetic outcomes for these interventions compare?
- Are these interventions cost-effective?

The first-line treatment of BCC is often surgical excision with predetermined margins. Numerous alternatives are available, including curettage, cryosurgery, laser, excision under frozen-section control, Mohs micrographic surgery (MMS – the use of horizontal frozen sections and mapping to determine tumor clearance), radiotherapy, topical therapy, intralesional therapy, photodynamic therapy (PDT – the application of a cream to induce photodamage to the tumor using various light sources), immunomodulators (agents used to stimulate the immune system and work on eradicating the tumor), and chemotherapy. Surgical treatment requires access to a minor operating room, and most other treatments are carried out in specialist centers. Although there is wide variety in the treatment modalities used in the management

of BCC, and the vast majority of the tumors are probably treated successfully, little research is available that accurately compares these different treatment modalities. The evidence cited in the following summaries refers to RCTs unless specified otherwise.

### Surgical excision

Five RCTs were found that compared surgical excision with other interventions [26–31].

No RCTs have investigated the margin of excision that would be effective in the removal of BCC by surgical excision with predetermined margins. Proxy measures based on Mohs micrographic surgical margins required to remove BCCs, and histopathological studies of excised specimens have suggested that, for small nodular or superficial BCC, a 4 mm margin of normal skin will clear 95% of tumors [21,32]. Larger margins are required for tumors greater than 20 mm and for morpheic tumors [21].

### Surgery versus photodynamic therapy

These studies are covered under the PDT section.

### Surgical excision with frozen-section margin control

One RCT of 347 patients compared surgical excision and frozen-section margin control with radiotherapy in primary BCC less than 40 mm in diameter on the face [33]. As shown in Table 33.1, the main outcome measure was persistent or recurrent disease at 4 years. The secondary end point was the cosmetic result assessed by the patient, the dermatologist, and three persons not involved in the trial.

### Efficacy

The 4-year failure rate was 0.7% (95% confidence interval [CI], 0.1–3.9%) in the surgery group and 7.5% (95% CI, 4.2–13.1%) in the radiotherapy group. Cosmetic outcome as assessed by five observers over the 4 years of the study consistently favored surgery [34]. At 4 years, 87% of patients assessed their cosmetic results as good after surgery and 69% after radiotherapy.

### Potential drawbacks

After radiotherapy, dyspigmentations and telangiectasia developed in more than 65% of the patients at 4 years. Radiodystrophy affected 41% of the patients at 4 years.

### Comment

Concealment of allocation was clear and the paper showed evidence of an a priori sample size calculation; however, the analysis was conducted on a per-protocol basis. Several previous studies have reported good cure rates and cosmetic results with surgery and radiotherapy; however, the above study was the first randomized trial giving an unbiased comparison of the two treatments.

### Implications for practice

The trial shows that the failure rate was significantly lower in surgery than in radiotherapy for the treatment of BCC of the face for lesions less than 4 cm in diameter. Surgery may also be preferred for its cosmetic result.

### Mohs micrographic surgery

MMS is a technique in which 100% of the surgical margin is examined by mapping horizontal frozen sections from successive excision layers until clearance is achieved. A large case series of BCC treated with MMS found the recurrence rate at 5 years to be 1% [35]. One RCT compared MMS with conventional surgical excision for high-risk BCCs of the face [28].

### Surgical excision versus Mohs micrographic surgery

One RCT [28] of 374 patients with 408 primary lesions and 204 patients with 191 recurrent lesions compared MMS with surgery. As shown in Table 33.1, the primary outcome was recurrence and the secondary outcome was incomplete excision, suboptimal esthetic results, and excessive costs of treatment.

### Efficacy

**Primary basal cell carcinoma** Recurrence at 30 months did not differ significantly between the groups: five of 171 (3%) in standard excision versus three of 160 (2%) for MMS (difference 1%; 95% CI, –2.5 to +3.7%;  $P = 0.724$ ).

**Recurrent basal cell carcinoma** Recurrence at 18 months did not differ significantly between the groups: three of 93 (3%) in standard excision versus none of 95 after MMS (difference 3.2%; 95% CI, –2.0 to +5%;  $P = 0.119$ ). The overall esthetic outcome did not differ significantly between MMS and standard excision. Primary

**Table 33.1** RCTs evaluating surgical excision in the treatment of BCC.

Study	Method	Participants	Interventions	Outcomes	Notes
Avril <i>et al.</i> 1997 [33] (France)	Single center Randomization by sequential sealed envelopes ITT	HP BCCs T1: 174, T2: 173 patients Histological type T1: 79 N, 52 ulcerated, 36 S and pagetoid, 7 sclerosing; T2: 74 N, 50 ulcerated, 41 S and pagetoid, 8 sclerosing Location T1: 53 nose, 36 eyelids, 36 forehead, 10 chin, 5 ear; T2: 49 nose, 42 cheek, 35 eyelids, 29 forehead, 12 chin, 6 ear	T1: surgery – resection of whole tumor with a free margin of at least 2 mm from visible borders; T2: radiotherapy – interstitial brachytherapy, superficial contract therapy or conventional therapy, chosen by radiotherapist according to tumor parameters and location and patient characteristics	FU: 3, 6, 12 months after end of treatment; then yearly until fourth year Rate of histologically confirmed persistent tumor or recurrence after 4 years Patients examined by dermatologists; photographs of scar taken at three standardized distances	Ex: BCC on scalp or neck, patients who had total removal of BCC at biopsy, with 5 or more BCCs, life expectancy <3 years
Smeets <i>et al.</i> 2004 [28] (Netherlands)	Multicenter, telephone randomization	HP primary or recurrent BCC, 1 cm diameter, high risk or aggressive histopathological subtype. Primary T1: 198, T2: 199; recurrent T1: 102, T2: 102 patients	T1: MMS; T2: surgery	FU: recurrence at 18 and 30 months	ITT analysis

BCC, basal cell carcinoma; Ex, exclusion; FU, follow-up; HP, histologically proven; ITT, intention to treat; MMS, Mohs micrographic surgery; N, nodular; PP, per protocol; S, superficial.

BCCs had a significantly better esthetic outcome than recurrent BCCs ( $P = 0.038$ ), and cosmetic results became significantly poorer with increasing defect size for both primary ( $r = 0.383$ ,  $P < 0.001$ ) and recurrent BCCs ( $r = 0.351$ ,  $P = 0.001$ ). Total operative costs for both primary and recurrent BCCs are higher for MMS than standard excision ( $P < 0.001$ ).

### Potential drawbacks

Thirty-one primary BCCs (18%) and 31 recurrent BCCs (32%) were incompletely excised on first excision in the standard excision group. Primary tumors with aggressive histopathology were significantly more likely to be incompletely excised than those of the nonaggressive type. No adverse events were reported.

### Comments

Concealment of allocation was clear, and an intention-to-treat analysis was used.

It was suggested that the groups might not have been large enough for a significant difference to be detected. This study used 3 mm margins for both treatments to standardize the two treatment modalities (smaller margins are usually used for MMS). If standard excision was incomplete, a reexcision with a 3 mm margin was done. If the margins remained positive after the second excision, then MMS was undertaken.

Compared with surgical excision, the total treatment costs of MMS were significantly higher [36].

### Implications for practice

This is the only RCT comparing MMS with surgical excision for patients with high-risk facial BCCs. Treatment with MMS slightly, but not significantly, lowered the recurrence rate for both primary and recurrent BCCs in comparison with surgical excision. Five-year follow-up data are needed to determine definite recurrence rates in both groups. Almost a quarter of all aggressive carcinomas of 1 cm or more in diameter and about a third of all recurrent carcinomas were incompletely excised with a 3 mm margin, and

therefore MMS may well be preferable to use for these tumors to avoid larger defects, poor esthetic outcome, and functional problems.

One further RCT found that preoperative tumor curettage in MMS was associated with an increase in wound size [37].

### Cryotherapy

Three RCTs were found and are summarized in Table 33.2.

### Cryotherapy versus radiotherapy

One study of 93 patients compared radiotherapy with cryotherapy for primary BCC, excluding lesions on the nose or pinna [38]. The aims of the study were to compare the control of the tumors with the two treatments, to assess the final cosmetic result, and to compare the discomfort and inconvenience experienced by the patient. Cryotherapy consisted of two freeze-thaw cycles, freezing for 1 min each time.

### Efficacy

Recurrence rates at 1 year were 4% (two of 49) in the radiotherapy group and 39% (17 of 44) in the cryotherapy group. At 2 years, no further tumors had recurred in either group. The cosmetic results for the two modes of treatment were not significantly different.

### Potential drawbacks

The degree of pain, discomfort, discharge, and bleeding from the treated areas was the same in both groups. Only one patient from each group was seriously inconvenienced by the treatment. Hypopigmentation was more common than hyperpigmentation with both modes of treatment (81% of those in the radiotherapy group and 88% of those in the cryotherapy group). Seven patients treated with radiotherapy developed some radiation telangiectasia. Hypopigmentation and telangiectasia tend to be lifelong. Five patients treated with cryotherapy developed milia, which all disappeared by 1 year.

**Table 33.2** RCTs evaluating cryotherapy in the treatment of BCC.

Study	Method	Participants	Interventions	Outcomes	Notes
Hall <i>et al.</i> 1986 [38] (UK)	Single center Method of randomization not known, PP	105 patients BP BCCs T1: 44; T2: 49 patients Sites: T1: 30 neck and face, 6 eyelids, 8 trunk; T2: 40 neck and face, 3 eyelids, 6 trunk	T1: cryotherapy using a Cry-Owen liquid-nitrogen spray gun; all lesions treated with two freeze-thaw cycles, freezing for 1 min each time, with a thaw time of at least 90 s; T2: radiotherapy (130 kV X-rays)	FU: recurrence of tumor and cosmetic appearance at 1, 6, 12, 24 months after treatment Tumor identified histologically	12 excluded: 5 died of other causes, 7 lost to FU Ex: recurrent tumors, lesions on nose or pinna, lesion near eye and vision in eye <6/18
Mallon and Dawber, 1996 [39] (UK)	Single center Method of randomization not known, PP	84 patients Mostly clinically proven BCCs Facial lesions $\leq 1.5$ cm not extending >3 mm below skin were included. T1: 36; T2: 48 patients Mean age T1: 67; T2: 69 years	T1: single 30 s freeze-thaw cycle T2: double 30 s freeze-thaw cycle	FU: T1: 10 months to 7.1 years; T2: 1.2–6.1 years Lesions assessed clinically	7 lost to FU, T1: 2, T2: 5
Thissen <i>et al.</i> 2000 [40] (Netherlands)	Single center Method of randomization not known, PP	103 patients Some BP BCCs Lesions S or N, <2 cm diameter, localized anywhere on the head and neck	T1: surgery T2: cryosurgery (no. 3 curette used to debulk the tumor; no. 1 used to remove remainder of BCC around the borders. Freezing: two freezing periods, each lasting 20 s)	FU: cosmetic and recurrence at 1 year Recurrence assessed clinically	Lost to FU: 3 in control group did not turn up for visits, 1 died (unrelated to treatment), 3 developed recurrent BCC (all T2)

BCC, basal cell carcinoma; BP, biopsy-proven; Ex, exclusion; FU, follow-up; HP, histologically proven; N, nodular; PP, per protocol; S, superficial.

**Comments**

The concealment of allocation was unclear, and the analysis was conducted on a per-protocol basis. There was no indication of the type of lesion.

**Implication for clinical practice**

Cryotherapy, although convenient and less expensive than radiotherapy, does not appear to have better cure rates than radiotherapy (especially for lesions >2 cm). Cosmetic effects for radiotherapy and cryotherapy are comparable. Variations in technique occur between different physicians and may account for differences in outcome. Lesions larger than 2 cm in diameter treated by cryotherapy recurred, but lesions larger than 2 cm and treated with radiotherapy were controlled. It was concluded that cryotherapy does not offer a satisfactory alternative to radiotherapy in the treatment of BCC.

**Cryotherapy: varying number of freeze–thaw cycles**

In a second RCT of 84 patients, one freeze–thaw cycle of 30 s was compared with two freeze–thaw cycles of 30 s for low-risk facial BCCs [39].

**Efficacy**

Recurrence rates were significant: 4.7% with two freeze–thaw cycles and 20.6% with one cycle after a median of 18 months.

**Potential drawbacks**

No mention was made of adverse effects of the treatment.

**Comments**

Concealment of allocation was unclear, and the analysis was conducted on a per-protocol basis. Only common facial lesions of 1.5 cm or less were included, and not all of the lesions were biopsied. Variations in technique between different physicians may account for differences in outcome.

**Implications for clinical practice**

Facial lesions require a double freeze–thaw cycle with liquid nitrogen if the high cure rates in many reports of formal excision or radiotherapy are to be achieved. Although case series suggest that higher clearance rates can be achieved, particularly with low-risk tumors, more prospective evidence is required.

**Cryotherapy versus surgical excision**

A third RCT of 96 patients [40] compared cryosurgery with surgical excision for BCC of the head and neck. The primary outcome was the cosmetic result, but recurrence rates in both groups were also compared. Recurrences were treated by surgical excision. Cosmetic results were judged by five independent professional observers and by the patients.

**Efficacy**

The recurrence rate for cryosurgery was three of 48 at 1 year, whereas in the surgery group no recurrences developed at 1 year. The cosmetic results after surgical excision generally received a significantly better evaluation in comparison with cryosurgery for superficial and nodular subtypes localized in the head/neck region.

**Comments**

Concealment of allocation was unclear. The analysis was conducted on a per-protocol basis, although the paper showed evidence of an a priori sample size calculation.

**Potential drawbacks**

Two patients (4%) developed secondary wound infections in the first and second weeks after surgery, for which systemic antibiotics were given. Ninety percent of the patients in the cryotherapy group complained of moderate to severe swelling of the treated area, followed by long-lasting leakage of exudates from the defect. After cryotherapy, three patients (6%) had secondary wound infection, for which systemic antibiotics were given.

**Implications for clinical practice**

Surgical excision for nodular and superficial lesions smaller than 2 cm is cosmetically more acceptable than cryosurgery. Cryotherapy does not appear to be a satisfactory alternative to surgery for superficial or nodular lesions in the head and neck area of less than 2 cm in diameter.

**Photodynamic therapy**

PDT is a nonionizing radiation treatment modality. It uses the interaction between visible light and tumor-sensitizing agents to generate cell death.

**Methyl aminolevulinate photodynamic therapy versus placebo**

Two multicentre RCTs, performed in Australia and the USA, with short follow-up periods of just 3 and 6 months, compared methyl aminolevulinate (MAL)–PDT with placebo [41], summarized in Table 33.3.

**Efficacy**

The results for the histologically verified lesion complete response rates were higher with MAL–PDT compared with placebo (73% (55/75) versus 27% (20/75)). Cosmetic outcome was good or excellent in 98% of evaluable, completely responding lesions treated with MAL–PDT.

**Methyl aminolevulinate photodynamic therapy versus 5-aminolevulinate photodynamic therapy**

Two studies [42,43] compared two topical photosensitizers, 5-aminolevulinate (ALA) and MAL.

**Efficacy**

The first study [42] randomized 43 nodular BCC to either ALA–PDT or MAL–PDT. Most tumors were debulked prior to PDT.

There was no significant difference in terms of clearance or pain scores between the two groups at 8 weeks after treatment; however, the cost of MAL–PDT was found to be sixfold higher compared with ALA–PDT.

The second study randomized 24 patients with 112 superficial BCCs to either ALA–PDT or MAL–PDT [43] and illuminated with a diode laser. There was no significant difference in lesion clearance at 12 weeks when ALA–PDT (44/72) was compared with MAL–PDT (23/40) ( $P = 0.9$ ).

Tumors were debulked prior to PDT.

**Photodynamic therapy versus surgery**

Four RCTs compared PDT with surgery [26,27,29–31], and these are summarized in Table 33.3.

The first RCT of 103 patients compared surgical excision versus MAL–PDT in primary nodular BCC of the face [26,27].

**Efficacy**

The response at 3 months was 98% for surgery versus 91% for PDT, difference 4.8% (95% CI, –3.4 to +13%). There was no significant

**Table 33.3** RCTs evaluating photodynamic therapy in the treatment of BCC.

Study	Method	Participants	Interventions	Outcomes	Notes
Wang <i>et al.</i> 2001 [45] (Sweden)	Single center Randomized according to a stratified randomization pattern in blocks of 10 patients, PP	HP BCC 44 women; 44 men; age range 42–88 years Type: T1: 22 S, 25 N; T2: 17 S, 24 N Distribution: 47 trunk, 25 head and neck, 10 legs, 6 arms	T1: PDT (20% weight-based ALA/ water-in-oil cream applied to lesion; irradiation 6 h later T2: cryosurgery (2 freeze–thaw cycles)	FU: 1, 4, 8 weeks, 3 months after treatment Last FU 12 months after first treatment Punch biopsy at 3 and 12 months	Ex: BCC on nose; M growth; porphyria; abdominal pain of unknown etiology; photosensitivity; treatment of BCC with topical steroids type III or IV within the last month
Soler <i>et al.</i> 2000 [48] (Norway)	Single center Randomization numbers in locked envelopes. The patients were randomly allocated on the treatment day to one of the two arms in blocks of four patients, ITT	HP BCC 83 patients 245 lesions	All lesions in both groups topical 20% ALA, removed after 3 h and light source applied T1: laser light (630 nm); T2: broadband light	FU: 3, 6 months after treatment Outcomes: complete, partial, or no response; cosmetic outcome and pain intensity during treatment and FU	
Foley <i>et al.</i> 2009 [41] (Australia, USA)	Two multicenter studies (similar design) Computer-generated randomization and stratified by center	HP N BCC, $n = 131$ (160 lesions) ( $\leq 5$ mm depth)	T1: MAL–PDT; T2: placebo. Surface debridement prior to treatment. MAL or placebo applied to lesion for 3 h and covered with an adhesive occlusive dressing. Wavelength, 570–670 nm; light dose, 75 J/cm <sup>2</sup> ; light intensity, 50–200 mW/cm <sup>2</sup>	FU: 3 and 6 months	Blinded outcome assessor
Lui <i>et al.</i> 2004 [49] (Canada)	Multicenter Method of randomization not given	54 patients (421 BP N or S BCC or Bowen disease) Age range 22–79 years, mean 55	Single i.v. infusion of 14 mg/m <sup>2</sup> of verteporfin followed 1–3 h later by 60, 120 or 180 J/cm <sup>2</sup>	FU: 6 months (biopsy-proven)	7 patients (51 tumors) lost to FU. Analysis PP
Basset-Seguin 2008 (Europe)	Multicenter, open randomized study Method of randomization not given. Analysis PP	118 patients (219 lesions) with S BCCs. T1: 60; T2: 58 patients. T1: gentle removal of surface prior to PDT	T1: MAL–PDT; T2: cryo (double freeze–thaw)	FU: 3, 12, 36 months	Abstract
Mosterd <i>et al.</i> 2008 [29] (Europe)	Randomization per tumor using a computer-generated random allocation scheme	149 patients (173 lesions) with N BCCs. T1: 85; T2: 88 lesions	T1: ALA–PDT; T2: SE (3 weeks prior to PDT a partial debulking under local anesthesia)	FU: 3, 6, 12, 18 months and 2, 3, 4, and 5 years	
Szeimies <i>et al.</i> 2008 [30] (Europe, Australia)	Multicenter, noninferiority study	196 patients (1.4 S BCC/ patient). T1: 100; T2: 96 patients	T1: MAL–PDT; T2: SE	FU: 3, 6, and 12 months	
Schleier <i>et al.</i> 2007 [43] (Germany)	Single center. Method of randomization not known Patient and therapist blinded to treatment	24 patients (112 lesions) with HP S BCC. T1: $n = 13$ ; T2: $n = 11$	T1: ALA–PDT; T2: MAL–PDT Treated for 3 h and then illuminated with a diode laser	FU: 12 weeks and 6 months (clinical examination)	
Kuijpers <i>et al.</i> 2006 [42] (Netherlands)	Single center Patients were blinded Method of randomization not known	N BCC anywhere on skin and periocular area and hairy scalp with clinical diameter $< 20$ mm. Arits <i>et al.</i> 2010 [47] (Netherlands)	Method of randomization not known. Stratified by patient age and tumor location	453 patients with S BCC T1: $n = 118$ ; T2: $n = 121$ ; T3: $n = 125$	T1: PDT; T2: imiquimod; T3: 5-FU	FU: 3 and 12 months	
Berroeta <i>et al.</i> 2007 [31]	Random allocation list generated by computer. Random allocations concealed in opaque envelopes. No blinding. Analysis ITT	31 patients with 40 N BCCs ( $< 2$ cm)	T1: ALA–PDT; T2: SE Superficial curettage before PDT treatment	FU: 3, 6, and 12 months	
Rhodes <i>et al.</i> 2004 and 2007 [26,27] (UK)	Multicenter, phone/fax randomization	HP, N BCC, T1: 52; T2: 49 patients (110 lesions)	T1: MAL–PDT (75 J/cm <sup>2</sup> red light (570–670 nm); T2: surgery (with 5 mm margin)	FU: clinical clearance at 3, 12 months after treatment. Cosmetic outcome at 3, 12 months. Cosmesis and lesion recurrence at 24 months and 5 years	Ex: high-risk BCC on face. 24% of lesions were retreated. Analysis PP

ALA, aminolevulinic acid; BCC, basal cell carcinoma; BP, biopsy-proven; Ex, exclusion; FU, follow-up; HP, histologically proven; ITT, intention to treat; M, morphea-like; MAL–PDT, methyl aminolevulinate photodynamic therapy; MMS, Mohs micrographic surgery; N, nodular; PDT, photodynamic therapy; PP, per protocol; S, superficial.

difference in clearance at 12 months (98% for surgery vs 85% for PDT) ( $P = 0.15$ ). At 5 years after last treatment, the sustained lesion complete response rate, estimated by the complementary log-log model, was 76% (95% CI, 59–87%) for MAL-PDT compared with 96% (95% CI, 84–99%) for surgery, per-protocol population ( $P = 0.01$ ). The cosmetic outcome was significantly better at 12 and 24 months on the patients' assessment and at 3, 12, and 24 months on investigator evaluation ( $P < 0.001$ ). Cosmetic outcome at 5 years was significantly better for MAL-PDT compared with surgery as assessed by the investigator ( $P = 0.007$ ) [27].

#### **Potential drawbacks**

Significantly more patients treated with MAL-PDT compared with those treated with surgery reported adverse events (52% vs 29%;  $P = 0.03$ ). Most of the adverse events were transient local reactions commonly associated with PDT, such as a burning sensation on the skin, pain in the skin, or erythema.

#### **Comments**

Concealment of allocation was clear, but the analysis was per-protocol. Lesions with an incomplete response to PDT at 3 months received a second treatment cycle and were evaluated 3 months later.

#### **Implications for clinical practice**

Long-term follow-up indicates superior efficacy of surgery to MAL-PDT in nodular BCC. There is a trend toward higher recurrence rates with PDT in comparison with surgery, and significantly more patients reported adverse events in the PDT group. However, PDT may be preferred for its cosmetic results.

#### **Efficacy**

The second RCT [29] compared fractionated ALA-PDT with surgery in 173 primary nodular BCCs. A 3-year interim analysis revealed cumulative incidence of failure as 2.3% for surgical excision and 30.3% for PDT ( $P = 0.001$ ).

The third RCT [30] was a noninferiority study of MAL-PDT versus surgery in 196 patients with primary superficial BCC. Clearance at 3 months for superficial BCC was 92.2% for MAL-PDT compared with 99.2% for surgery, confirming the noninferiority hypothesis. At 12 months, 9.3% of the lesions recurred in MAL-PDT compared with none in the surgery group. Cosmetic outcome was statistically superior for MAL-PDT at all times.

The fourth study [31] randomized 31 patients with 40 nodular BCC to ALA-PDT or surgery. There was no significant difference in number of lesions that cleared at 1 year (13/21 ALA-PDT vs 15/19 surgery). PDT was significantly more painful than surgery during treatment (median pain 5/10 for PDT vs 0/10 for surgery,  $P = 0.24$ ). There was no significant difference in cosmetic outcome. Although not statistically significant, there were no persistent BCCs in the surgery group, but five lesions persisted in the PDT group.

#### **5-Aminolevulinic photodynamic therapy versus laser versus laser plus 5-aminolevulinic photodynamic therapy**

One study [44] compared ALA-PDT versus YAG laser ablation versus YAG laser ablation plus ALA-PDT for recurrent nodular BCC.

#### **Efficacy**

Combination therapy demonstrated the most effective treatment at all time points, with a final efficacy of 98.97% versus 94.85% (PDT

only) and 91.75% for YAG laser only. The combination therapy also gave the best esthetic results.

#### **Photodynamic therapy versus cryotherapy**

One RCT of 88 patients compared PDT with cryotherapy with two freeze-thaw cycles for BCC [45].

#### **Efficacy**

There was no significant difference in recurrence rates at 12 months, and both were quite high. Histological recurrence rates at 1 year were 25% (11 of 44) in the PDT group, compared with 15% (six of 39) in the cryotherapy group, despite multiple retreatments in the PDT group. Scarring and tissue defects scored significantly better following PDT.

A second study of 118 patients [46] compared MAL-PDT versus cryotherapy for superficial BCC. Cumulative recurrence rates at 5 years follow-up was 22% (22/100) in MAL-PDT and 20% (19/93) for cryotherapy ( $P = 0.86$ ). Recurrence at 1 year was 8% (eight of 97) in the PDT group, compared with 16% (15 of 91) in the cryotherapy group. At 36 months, the estimated complete response rate was 74% for both groups. More people had an excellent cosmetic outcome with MAL-PDT than with cryotherapy at 5 years (56% (18/32) versus 14% (6/43);  $P = 0.00078$ ).

#### **Potential drawbacks**

In the first study, more patients indicated pain and discomfort during and after treatment with PDT, but the differences were not statistically significant.

#### **Comments**

For the first study, concealment of allocation was clear. For both studies, the analysis was conducted on a per-protocol basis and no sample size calculation was given.

#### **Implications for clinical practice**

Although tolerability for patients was greater and cosmetic outcomes were considered better in the PDT group, the published efficacy data to date support the use of PDT for superficial BCC but do not support the introduction of PDT for the treatment of nodular BCC. Further studies demonstrating greater efficacy are needed, and follow-up periods for outcome assessment should be 3–5 years.

#### **Photodynamic therapy versus imiquimod versus 5-fluorouracil**

One study (abstract) [47] randomized 453 patients with 453 superficial BCC to PDT, imiquimod, or 5-fluorouracil (5-FU).

#### **Efficacy**

Interim analysis indicate that all three modalities are almost equally effective with a good cosmetic result. Treatment failure at 3–12 months occurred in 12% (5/42) in the PDT group, 5% (3/56) in the imiquimod group and 6% (3/51) in the 5-FU group. At 3 months, 66% in the PDT group, 62% in the imiquimod group, and 53% in the 5-FU group had good to excellent cosmetic results.

#### **Laser versus broadband halogen light**

Another RCT [48] of 83 patients compared the clinical and cosmetic outcomes of superficial BCCs using either laser or broadband halogen light in PDT with topical ALA.

### Efficacy

At the end of the study (6 months), 86% in the laser group and 82% in the broadband halogen group were evaluated as having complete responses by both investigators. The study showed no significant differences in the cure rate ( $P = 0.49$ ; 95% CI,  $-7$  to  $+14\%$ ) or cosmetic outcome ( $P = 0.075$ ) between light exposure from a simple broad lamp with continuous spectrum (570–740 nm) or from a red-light laser (monochromatic 630 nm).

### Potential drawbacks

Eighty-three percent of patients receiving PDT with laser light and 76% of those receiving PDT with broadband halogen light reported some discomfort during and after illumination. Sixty-eight percent of the patients who received laser light and 74% of the patients who received broadband halogen light reported some degree of discomfort (stinging, itching, pain, headache, sensation of warmth, or blushing) during the first week of treatment. No serious adverse events were reported during the 6-month follow-up.

### Comments

Although 83 patients were involved, 245 superficial BCCs were included in the study, indicating more than one lesion per patient. Concealment of allocation was clear, and analysis was carried out on an intention-to-treat basis; however, no sample size calculation was included.

### Implications for practice

The results show that topical ALA-based PDT with a broadband halogen light source gives short-term (6 months) cure rates and a cosmetic outcome similar to those obtained with a laser light

source, although both are considerably inferior to excisional surgery. Reduced costs, increased safety, and the possibility of general use by dermatologists are other elements in favor of the lamp as a suitable light source.

### Verteporfin and red light: a dose-ranging study

One RCT [49] compared three different light doses in 54 patients with 421 multiple BCCs and found a dose response for histological clearance 6 months after treatment (nodular BCC 76–100% and superficial BCC 63–97%) (Table 33.3).

### Implications for practice

There is a need for long-term follow-up in order to identify the correct light dose, balancing response and cosmetic appearance.

### Intralesional interferon therapy

Interferons are naturally occurring glycoproteins that exhibit antiviral, antitumor, and immunomodulatory activities. Four RCTs were found (Table 33.4).

### Interferon alfa-2a and/or -2b

#### Efficacy

In the first trial [50], 45 patients were randomly assigned to receive 15 or 30 million units of interferon alfa-2a or -2b, or both interferon alfa-2a and -2b. The aim of the study was to evaluate the effectiveness of the interferons alone and whether this effect might be increased by their combination. The complete response at 8 weeks was similar, at 66–73% in each treatment group. No significant differences were found between the groups in this respect.

**Table 33.4** RCTs evaluating intralesional interferon in the treatment of BCCs

Study	Method	Participants	Interventions	Outcomes	Notes
Alps et al. 1996 [50] (Turkey)	Single center Method of randomization not known ITT	45 patients HP BCC T1: 15; T2: 15, T3: 15 patients Mean age T1: 58.7, T2: 63.6, T3: 60.3 years Histological types T1: 12 N, 1 S, 2 M; T2: 11 N, 2 S, 2 M; T3: 11 N, 2 S, 2 M	T1: INF alfa-2a; T2: INF alfa-2b; T3: INF alfa-2a and -2b	FU: cytologic specimens taken 8 weeks after completion of therapy; all cases evaluated clinically and histologically	Ex: Recurrent lesions, genetic or nevus conditions, deep tissue involvement
Cornell et al. 1990 [51] (USA)	Multicenter (4) Randomization by computer-generated PP	T1: 123; T2: 42 patients BP BCC Mean age T1: 56; T2: 57 years Histological type T1: 57 S, 66 N ulcerative; T2: 19 S, 23 N	T1: intralesional injections 1.5 million IU IFN alfa-2b; T2: vehicle for IFN preparation 3 alternate days/week for 3 consecutive weeks	FU: weekly after each of the three treatments. then at 5, 9, 13 weeks after completion of treatment, then every 3 months to 52 weeks	Ex: Previously received therapy to test site, immunosuppressive or cytotoxic therapy (within previous 4 weeks), or exogenous IFN/IFN alfa-2b (Intron A), debilitating illness, lesion in perioral or central area of the face or penetrating to deep tissue
Edwards et al. 1990 [52] (USA)	Single center Method of randomization not known, PP	T1: 33; T2: 32 patients BP BCC Age range 35–65 years Histological type T1: 16 S, 17 N; T2: 15 S, 15 N	10 million IU zinc chelate IFN alfa-2b; T1: single injection; T2: one dose per week for 3 weeks	BCC measured, photographed before each treatment and at beginning of weeks 2, 8, 12, and 16 after the first injection Biopsy at week 16	Ex: thromboembolic disease, radiation therapy to the test site area, history of arsenic ingestion, pregnancy, immunosuppression, receiving nonsteroidal anti-inflammatory drugs, M BCC, recurrent cancers, deeply invasive lesions, periorificial tumors, central facial BCC
Rogozinski et al. 1997 [53] (Poland)	Single center Method of randomization not known, ITT	T1: 17; T2: 18 patients	T1: recombinant INF beta; T2: placebo	FU: 16 weeks after treatment and 2 years	

BCC, basal cell carcinoma; BP, biopsy-proven; Ex, exclusion; FU, follow-up; HP, histologically proven; IFN, interferon; M, morphea-like; N, nodular; PP, per protocol; S, superficial.

**Potential drawbacks**

One drawback is pain at the injection site. All patients had flu-like syndrome (fever, chills, headaches, fatigue, myalgia), especially within the first 2 weeks after the initiation of interferon therapy.

**Comments**

Concealment of allocation was unclear; however, the analysis was performed on an intention-to-treat basis.

**Implications for clinical practice**

Combining interferon alfa-2a and -2b does not appear to increase their effectiveness.

**Interferon alfa-2b versus vehicle**

Another trial of 165 patients [51] compared interferon alfa-2b at 1.5 million units three times weekly for 3 weeks with vehicle in a 3:1 ratio of interferon-treated to placebo-treated patients.

**Efficacy**

Eighty-one percent of interferon-treated patients were clinically and histologically cured at 52 weeks, compared with 20% of the placebo recipients. The cure rate was independent of lesion type or size.

**Potential drawbacks**

Flu-like symptoms occurred more commonly in the interferon-treated group.

**Comments**

Concealment of allocation was clear; however, the analysis was conducted on a per-protocol basis. Interestingly, 20% of the patients treated with vehicle appeared to have a histological cure at 1 year. Longer term studies are needed to determine whether this is genuine.

**Implications for clinical practice**

Interferon alfa-2b has not been compared with current standards of surgical or radiotherapy cures and so cannot be recommended as a first-line therapy. Interferon alfa-2b could be considered for patients who are not candidates for simple surgery or who desire nonsurgical therapy.

**Number of dosages of interferon alfa-2b**

A third RCT [52] compared a single dose of 10 million IU pro-tamine zinc chelate interferon alfa-2b (a sustained-release preparation) with the same dose weekly for 3 weeks in 65 patients. Histological cure rates at 16 weeks were 52% and 80% for one and three doses weekly, respectively, and the cosmetic effect was graded as excellent by 51% of the patients. Side effects were similar for both the single-dosage and repeated-dosage groups, and were those common to interferon (Table 33.4).

**Implications for clinical practice**

Refinement of the formulation to improve the release of interferon in order to help minimize side effects has not been realized. A trial is needed to compare the sustained-release formulation of interferon alfa-2b with standard interferon alfa-2b.

**Interferon beta**

Recombinant interferon beta at 1 million units three times weekly for 3 weeks has been compared with placebo in a trial of 35 patients [53].

**Efficacy**

After 2 years of follow-up, 47% of patients in the treatment group showed a complete response, compared with none in the placebo group.

**Potential drawbacks**

Inflammation at the injection site was found in 11 of the 16 patients in the treatment group and four of the 18 receiving placebo.

**Comment**

The analysis was conducted on a per-protocol basis; concealment of allocation is not known.

**Implications for clinical practice**

The paper suggests recombinant interferon beta as an alternative treatment for BCC. The response rate at 47% is too low for it to be recommended as a treatment for BCC.

**BEC-5 cream**

BEC-5 is a mixture of 0.005% solasodine glycosides found in solanaceous plants (aubergine). BEC-5 cream binds to endogenous ectins and shows preferential cytotoxicity to human cancer cells.

In a double-blind randomized trial, BEC-5 cream was compared with matching vehicle [54] (Table 33.5). Biopsy-proven lesions, excluding morpheic BCC, were treated twice daily under occlusion with BEC-5 or vehicle for 8 weeks.

**Efficacy**

At 8 weeks, significantly more tumors cleared in the BEC-5 group compared with the vehicle group (66% (41/ 62) vs 25% (8/32);  $P = 0.001$ ) The cure rates after 1 year were also significantly different: 52% (32/62) in the BEC-5 group and 16% (5/32) in the placebo group.

**Potential drawbacks**

There were no major treatment-related adverse effects.

**Comment**

Concealment of allocation was unclear, and the analysis was conducted on an intention-to-treat basis.

**Table 33.5** RCTs evaluating BEC-5 in the treatment of BCC.

Study	Method	Participants	Interventions	Outcomes	Notes
Punjabi <i>et al.</i> 2008 [54] (UK)	Multicenter method of randomization not known	94 patients BP BCC Age 32–95 years	T1: BEC-5; T2: vehicle; twice daily under occlusion for 8 weeks	Patients reviewed every 2 weeks Repeat punch biopsy at 8 weeks in 84 patients	10 patients in T1 did not complete the study

BCC, basal cell carcinoma; BP, biopsy-proven.

**Implications for clinical practice**

Although significant differences were found between the groups, the cure rate is not sufficiently high in comparison with other treatments for this method to be recommended.

**PEP005 (ingenol mebutate) gel**

A dose-finding phase IIa study [55] randomized 60 patients with superficial BCC to two different treatment regimens for ingenol mebutate gel – and within each arm, different concentrations of ingenol mebutate gel or vehicle.

**Efficacy**

Efficacy appeared to be dose related. Overall, complete clinical and histological lesion clearance rates were highest with ingenol mebutate gel, 0.05%. Further studies need to be undertaken.

**5-Fluorouracil applied topically**

The primary mechanism of action of 5-FU is thought to be inhibition of DNA synthesis by competitive inhibition of thymidylate synthetase [56].

**5-Fluorouracil in phosphatidylcholine versus 5-fluorouracil in petrolatum**

A double-blind randomized pilot study [57] of 5-FU 5% cream in phosphatidylcholine (PC) vehicle was compared with 5-FU 5% in petrolatum. Further details of this study are given in Table 33.6. PC was used as a vehicle to facilitate the penetration of 5-FU.

**Efficacy**

Histological cure at week 16 was 90% with the PC vehicle and 57% with the petrolatum-based cream. The patients also evaluated the treatment site on each visit for cosmetic appearance. No differences were detected in the clinical appearance or adverse effects between the two therapeutic arms of the study.

**Comments**

The study was not adequately powered to detect any statistically significant differences in outcome between the groups, and concealment of allocation was unclear; however, the analysis was conducted on an intention-to-treat basis.

**Potential drawbacks**

Local irritation, erythema, ulceration, and tenderness were common reactions, but were well tolerated by the patients. Minimal itching and discomfort were experienced by some of the patients in both treatment arms.

**Implications for clinical practice**

The study may indicate an increase in short-term eradication of BCC using a PC-based vehicle in comparison with conventional petrolatum-based formulations of 5-FU. There was an excellent cosmetic outcome in all treatment sites before excision at week 16. Further large-scale double-blind trials with long-term follow-up periods of 3–5 years are needed to establish the efficacy of this treatment modality.

**5-Fluorouracil–epinephrine injectable gel**

An open-label randomized study of 122 patients [58] tested the safety, tolerability, and efficacy of six treatment regimens of 5-FU–epinephrine gel. Two doses and four treatment schedules were used (Table 33.6).

**Efficacy**

Overall, the average response rate for the six regimens was 91%, as defined by the absence of any tumor on the basis of histological analysis of excised specimen. A 100% complete response rate was observed in patients who received 5 mL 5-FU–epinephrine gel twice weekly for 4 weeks – a 92% response rate for superficial lesions and a 91% response rate for nodular lesions.

All regimens appeared to work well and there were no statistically significant differences between them. The various treatment regimens with higher doses and/or treatment frequency resulted in higher complete response rates than obtained in an earlier pilot study [59]. The cosmetic appearance of the lesion site prior to excision at 3 months ranged from good to excellent.

**Potential drawbacks**

All patients had transient, moderate to severe stinging, burning, or pain at the time of injection. Local tissue reactions were confined to the treatment site and included erythema, swelling, desquamation, erosions, and eschar in most patients. Hyperpigmentation was

**Table 33.6** Randomized controlled trials evaluating 5-fluorouracil (5-FU) in the treatment of basal cell carcinoma.

Study	Method	Participants	Interventions	Outcomes	Notes
Romagosa <i>et al.</i> 2000 [57] (USA)	Single center Method of randomization not known ITT	13 patients, 17 BP non-S BCCs $\geq 0.7$ cm greatest diameter	T1: 5% 5-FU in PC vehicle T2: 5% 5-FU in petrolatum base Applied a.m. and p.m. for 4 consecutive weeks	FU: every 4 weeks for 16 weeks Final visit was biopsy of site	Ex: systemic disease, women of childbearing age, facial BCCs
Miller <i>et al.</i> 1997 [58] (USA)	Multicenter, randomized, open-label Method of randomization not known PP	97 males, 25 females Single BP BCC Mean age 61 years Histological type: 38 S, 85 N Location: 9 head, 9 neck, 38 upper extremities, 11 lower extremities, 55 trunk Lesion area median 80 mm <sup>2</sup>	6 treatment regimens with 5-FU/epi gel: T1: 1.0 mL once weekly for 6 weeks; T2: 0.5 mL once weekly for 6 weeks; T3: 1.0 mL twice weekly for 3 weeks; T4: 0.5 mL twice weekly for 3 weeks; T5: 0.5 mL twice weekly for 4 weeks; T6: 0.5 mL three times weekly for 2 weeks	FU examinations of patients at 1, 4, 8, 12 weeks after last injection At each visit, patient and investigator gave subjective evaluation of cosmetic appearance of lesion	Ex: high-risk sites. Lesions with deep tissue involvement, basal cell nevus syndrome, hypersensitivities or allergies to 5-FU, sulfites, epinephrine, bovine collagen, history of autoimmune disease, pregnancy. Six patients were lost to follow-up

BCC, basal cell carcinoma; BP, biopsy-proven; Ex, exclusion; FU, follow-up; 5-FU, 5-fluorouracil; ITT, intention to treat; N, nodular; PP, per protocol; S, superficial.

observed in 83% of the patients, but typically cleared up during the follow-up period. Forty-seven percent of the patients had ulcerations at the treatment site. The lowest incidence and severity of reactions occurred with 0.5 mL 5-FU–epinephrine gel three times weekly for 2 weeks.

### Comments

The analysis was per protocol. Concealment of allocation was unclear. No sample size calculation was described.

### Implications for clinical practice

High local drug concentrations can be maintained for longer with the epinephrine gel delivery of 5-FU. A trial of 5-FU–epinephrine gel versus surgical excision, monitoring adverse effects, is required to confirm the claim that the response rates are comparable to those with surgery.

### Imiquimod

Imiquimod is an immune-response modifier. It induces cytokines that promote a TH1 lymphocyte or cell-mediated immune response [60–62]. These cytokines include interferon alfa and gamma, and interleukin-12. In animal studies, imiquimod has demonstrated broad antiviral and antitumor effects that are largely mediated by interferon alfa [61]. In humans, imiquimod 5% cream is safe and effective in the treatment of external anogenital warts [63,64]. More recently, imiquimod has been licensed in the UK for superficial BCC. We found 10 RCTs, which are summarized in Table 33.7.

### Efficacy compared with vehicle cream

One study of 35 patients evaluated the safety and efficacy of imiquimod 5% cream in the treatment of superficial and nodular BCC [65,66]. This small trial suggested short-term success rates similar to those of excision surgery, with the added advantage of no scarring.

In a phase II dose–response trial of imiquimod 5% cream applied for 6 weeks in 99 Australian patients with primary superficial BCC [67], histological clearance rates (defined as patients with no histological evidence of BCC when the site of the treated lesion was excised 6 weeks after imiquimod treatment) were 100% (all of three), 88% (29 of 33), 73% (22 of 30), and 70% (23 of 33) for twice daily, once daily, six times weekly, and three times weekly regimens, respectively.

Another similar multicenter RCT of 128 patients with superficial BCC compared imiquimod twice daily, once daily, 5 days/week, and 3 days/week with vehicle using the same end points [68]. The intention-to-treat analysis showed clearance rates of 100% (10 of 10), 87% (27 of 31), 81% (21 of 26), and 52% for the twice daily, once daily, 5 days/week, and 3 days/week groups, respectively. Interestingly, there was a small vehicle response rate: 19% (six of 32).

Pooled data from two identical industry-funded studies [69] conducted in the USA in 724 patients with superficial BCC compared imiquimod daily either five times per week or seven times per week for 6 weeks versus vehicle. The histological clearance rates for the five times weekly and seven times weekly imiquimod groups were 82% and 79%, respectively.

One further industry-sponsored trial conducted in Europe [70] in 166 patients evaluated imiquimod 5% cream for the treatment of superficial BCC. At 12 weeks posttreatment, composite clearance was demonstrated in 77% (95% CI, 67–85%) and 6% (95% CI,

3–13%) of patients treated with imiquimod and vehicle cream, respectively ( $P < 0.001$ ), and histological clearance was demonstrated in 80% (95% CI, 70–87%) and 6% (95% CI, 3–13%), respectively ( $P < 0.001$ ).

Two similar studies [71] of 93 and 90 patients with superficial BCC and nodular BCC, respectively, found no significant difference in the treatment failure rate when occlusion was used.

Two further industry-sponsored trials [72] conducted in the USA have evaluated imiquimod 5% cream for the treatment of nodular BCC. One study reported histological clearance rates of 71% (25 of 35) for once-daily treatment for 6 weeks. Another vehicle-controlled RCT of 92 patients with nodular BCC who underwent treatment for 12 weeks using twice daily, once daily, 5 days/week, or 3 days/week reported intention-to-treat histological clearance rates of 75% (three of four), 76% (16 of 21), 70% (16 of 23), and 60% (12 of 20), respectively, with a vehicle response rate of 13% (three of 24).

One study [73] compared the tolerability of two regimens for the treatment of superficial BCC (Table 33.7). There was no significant difference in clearance rate at 19 weeks; however, there was a significant difference at 52 weeks (43% vs 88%) in favor of 5% imiquimod cream once daily with a 1 week interval. Both regimens were well tolerated.

One study [74] compared imiquimod three times a week over 8 weeks versus three times a week over 12 weeks in patients with nodular BCC. There were no significant differences between the treatment arms with respect to efficacy or tolerability. Clinical clearance was found in 70/90 patients. Histopathological clearance was seen in 58 patients. In 12 patients, despite complete clinical clearance, tumor was still detected in histopathological evaluation.

### Potential drawbacks

There may be some local skin reaction to the cream, including: redness, edema, skin hardening, vesicles, erosion, ulceration, flaking, and scabbing. These brisk inflammatory reactions, at least clinically, would be consistent with an acute immunologic reconstitution of the sun-damaged skin, resulting in an immunologically mediated elimination of malignant and premalignant cells. In all studies, local reactions were common, mostly mild or moderate, were well tolerated by patients, and declined in incidence and severity with less frequent dosing [65–67,69,71,72].

### Comment

There was no long-term follow-up for recurrence, which is very important for assessing treatments. Increasing severity of erythema, erosion, and scabbing/crusting was associated with higher clearance rates. Patients were able to apply the cream themselves in all of the trials – a feature that could reduce the need for attendance at busy hospital departments for low-risk lesions.

Clinical clearance does not accurately reflect the presence or absence of disease.

### Implications for clinical practice

Topical imiquimod could become a useful treatment for superficial and low-risk BCCs and would allow dermatologists to concentrate on the high-risk BCCs, but long-term results comparing topical imiquimod with excisional surgery are essential. A study of this type has just been completed and the protocol has been published [75]. The results for treatment success at 3 years (primary outcome) have been submitted for publication by the authors of this chapter.

**Table 33.7** Randomized controlled trials evaluating imiquimod 5% cream in the treatment of basal cell carcinoma

Study	Method	Participants	Interventions	Outcomes
Beutner <i>et al.</i> 1999 [65] (USA)	Single center Randomization to give 2:1 ratio of imiquimod cream to vehicle cream Method of randomization not known ITT	Age range 37–81 years BP BCCs, T1: 7; T2: 4; T3: 4; T5: 5; T6: 11 patients Size: 0.5–2.0 cm <sup>2</sup> Mainly upper body Histological type, T1: 1 N, 2 S; T2: 1 N, 3 S; T3: 4 S; T4: 2 N, 3 S; T5: 2 N, 2 S; T6: 1 N, 10 S	Imiquimod 5% cream, T1: twice/day; T2: once/day; T3: three times/week; T4: twice/week; T5: once/week; T6: vehicle	FU: 6 weeks after treatment. Tumor site excised and examined histologically
Marks <i>et al.</i> 2001 [67] (Australia, New Zealand)	Multicenter Method of randomization not known ITT	72 male, 27 female HP S BCC; surface area 0.5–2.0 cm <sup>2</sup> Location: 32% upper limbs, 28% trunk, 40% head and neck	Imiquimod 5% cream: T1: twice/day; T2: once/day; T3: twice/day for 3 days/week; T4: once/day for 2 days/week	FU: 1, 2, 4, 6 weeks Excision at week 6 Lost to FU, T2: 2 (pruritus); T3: 1 (cerebrovascular accident); T4: 1 (excision of nearby tumor)
Geisse <i>et al.</i> 2002 [68] (USA)	Multicenter, randomized, blinded, vehicle-controlled dose–response Method of randomization not known ITT	128 patients. Single, primary BP S BCC (0.5–2.0 cm <sup>2</sup> )	Imiquimod for 12 weeks, T1: twice daily; T2: once daily; T3: Mon–Fri; T4: Mon, Wed, Fri	FU: surgical excision 6 weeks after treatment
Sterry <i>et al.</i> 2002 [71] (Europe)	Multicenter, randomized open-label, dose–response Method of randomization not known ITT	Two studies. HP BCC. 93 N BCC (0.5–2.0 cm <sup>2</sup> ), 90 S BCC (0.25–1.5 cm <sup>2</sup> )	T1/T2: imiquimod 3 times/week for 6 weeks with (T1) and without (T2) occlusion; T3/T4: twice/week for 6 weeks, with (T3) and without (T4) occlusion	FU: surgical excision 6 weeks after treatment
Shumack <i>et al.</i> 2002 [72] (USA)	Two studies: multicenter, randomized, open-label, dose–response and a multicenter, randomized, blinded, vehicle-controlled dose–response Method of randomization not known ITT	Study 1: 99 patients, single, primary, BP N BCC (0.5–2.0 cm <sup>2</sup> ) Study 2: 92 patients, single, primary BP N BCC (0.5–2.0 cm <sup>2</sup> )	Study 1: imiquimod for 6 weeks, T1: twice daily; T2: once daily; T3: twice daily 3 days/week for 6 weeks; T4: 3/week for 6 weeks Study 2: imiquimod for 12 weeks, T1 twice daily; T2: once daily; T3: Mon–Fri; T4: Mon, Wed, Fri	FU: surgical excision 6 weeks after treatment
Schulze <i>et al.</i> 2005 [70] (Europe)	Multicenter, randomized, double blinded, vehicle-controlled Computer-generated randomization schedule ITT	166 patients, HP S BCC on limbs, trunk, neck, or head. Not high-risk areas. Minimum area 0.5 cm <sup>2</sup> and maximum diameter 2.0 cm	Imiquimod 5% cream or vehicle daily, 7×/week for 6 weeks	FU: excised 12 weeks posttreatment
Geisse <i>et al.</i> 2004 [69] (USA)	Multicenter, randomized, double-blinded, vehicle-controlled. Computer-generated randomization schedule ITT	724 patients with BP S BCC, (0.5 cm <sup>2</sup> in area with max. diameter of 2 cm)	Imiquimod 5% cream or vehicle, daily either 5×/week or 7×/week for 6 weeks	FU: weeks 4 and 12 posttreatment
Ezughah <i>et al.</i> 2008 [73] (UK)	Computer-generated randomization schedule	32 patients with S BCC (minimum area 0.5 cm <sup>2</sup> and maximum depth of 2 mm), T1: 15; T2: 16 patients	Imiquimod (two different regimens), T1: 8 weeks treatment with once daily dose for alternate weeks; T2: 5 weeks treatment, once daily dose with 1-week interval in the middle of course	FU: 19 and 52 weeks
Eigentler <i>et al.</i> 2007 [74] (Germany)		102 patients with N BCC randomized Evaluable (N = 90)	Imiquimod thrice-weekly for either 8 or 12 weeks	12 patients dropped out

BCC, basal cell carcinoma; BP, biopsy-proven; FU, follow-up; HP, histologically proven; ITT, intention to treat; N, nodular; S, superficial.

Imiquimod has also been explored as adjuvant therapy for patients undergoing other treatment, but these studies are not covered in this chapter.

### Systemic therapy for basal cell carcinoma

Vismodegib is a small-molecule systemic inhibitor of the hedgehog Hh intracellular signaling pathway that is inactive in adults. This pathway is active in BCCs and in patients with nevroid BCC syndrome. Vismodegib is licensed for treatment of metastatic and locally advanced recurrent tumors inappropriate for surgery or radiotherapy. In an open-label, two-cohort Phase 2 study of meta-

static BCC and locally advanced BCC, a 30.3% partial response rate was seen with no complete responses in metastatic BCC and a 43% response in locally advanced disease with 21% of these having complete response [77]. In an RCT of vismodegib versus placebo in the treatment of 41 patients with basal cell nevus syndrome [78], treatment was associated with a reduction from an average of 29 tumors per participant during the observation period of 8 months to two and the safety committee stopped the placebo arm of the trial. Many tumors cleared histologically during treatment; however, 54% withdrew due to side effects, particularly dysgeusia/ageusia, weight loss, muscle cramps, and hair loss. Stopping treatment was

associated with the return of the original tumors but a reduced new tumor burden developing in the period of observation so far. Adverse effects settled within 4 weeks of stopping therapy.

This is clearly an interesting development in the management of advanced BCC, but further work is needed to define the best clinical situations and dosage regimes for the use of this agent, especially in view of the troublesome side effects.

### Key points

- Despite the enormous amount of work involved in the treatment of BCC, there are still very few good-quality RCTs concerning the efficacy of the treatment modalities used.
- Surgery and radiotherapy appear to be the most effective treatments.
- The majority of studies have been performed on low-risk BCCs, the results of which are probably not applicable to tumors of the morpheic type shown in Figure 33.3.
- Cryotherapy, although convenient and less expensive than surgery or radiotherapy, has poor cure rates in comparison with surgery or radiotherapy (especially for lesions >2 cm). The cosmetic effect is better with surgery and comparable to radiotherapy.
- If cryosurgery is to be used, two freeze-thaw cycles are recommended for nodular and superficial facial lesions (Figures 33.1 and 33.2) if cure rates approaching equivalence to those with formal excision or radiotherapy are to be achieved.
- Greater efficacy needs to be demonstrated for PDT in nodular BCC and interferon before they can be recommended.
- A broadband halogen light source may give cure rates and cosmetic outcome similar to laser light PDT, with the possible benefits of reduced costs, increased safety, and ease of use, although both are inferior to surgery.
- The efficacy of interferon alfa has not been directly compared with standard surgical treatment; interferons are associated with significant side effects, which may overshadow their usefulness, especially in the elderly. Interferon therapy requires several clinic visits.
- Increased short-term eradication of BCC using 5-FU in a PC-based vehicle to increase penetration should be compared with surgery, with long-term follow-up.
- Preliminary studies suggest a high success rate (87–88%) for imiquimod in the treatment of superficial BCC using a once-daily regimen for 6 weeks, and a useful (76%) treatment response when treating nodular BCC for 12 weeks. A long-term study has just been completed with excision surgery as a comparator.
- All future RCTs of BCC treatment should include 3–5-year outcomes, as short-term (less than 1 year) improvement may simply be a temporary phenomenon. This is especially important for topical application, which may appear to improve the surface of the lesion only to leave deeper extensions that the dermatologist may find it difficult to see on clinical examination.

### Vismodegib in advanced basal-cell carcinoma

- Hedgehog antagonist GDC-0449 in the treatment of advanced basal cell carcinoma – initial studies have shown that GDC-0449 has shown significant inhibitory activity in the treatment of advanced BCC [76].

# Primary cutaneous T-cell lymphoma

Fiona Child and Sean Whittaker

St John's Institute of Dermatology, Guy's and St Thomas NHS Foundation Trust, London, UK

## Background

### Definition

Primary cutaneous T-cell lymphomas (CTCLs) represent a heterogeneous group of extranodal non-Hodgkin's lymphomas, of which mycosis fungoides (MF) and Sézary syndrome (SS) are the most common clinicopathological subtypes [1]. MF is characterized by distinct clinical stages of cutaneous disease consisting of patches/plaques, tumors, and erythroderma in which the whole skin is involved. Peripheral adenopathy may or may not be present. SS is defined by the presence of erythroderma, peripheral lymphadenopathy, and a minimum number of Sézary cells within the peripheral blood. These clinicopathological entities are closely related pathogenetically, but are distinct from other less common types of primary CTCL.

### Incidence and prevalence

The overall annual incidence of primary CTCL is 7.7/1 000 000 person-years (MF or SS 4.1/1 000 000) with a male predominance [2]. However, the prevalence is much higher, because most patients have low-grade disease and live long [3]. Males and the black population are affected more commonly [2–4]. The incidence has increased during the past two decades, but this almost certainly partly reflects improved diagnosis of earlier stages and better registration, particularly in the USA [4].

### Etiology

The underlying etiology is unknown. There is evidence for inactivation of key tumor suppressor genes and TH2 cytokine production by tumor cells in MF/SS, but no disease-specific molecular abnormality has yet been identified [4]. Primary CTCL must be distinguished from human T-lymphotropic virus type-1 (HTLV-I)-associated adult T-cell leukemia lymphoma (ATLL), in which skin involvement often closely mimics the clinicopathological features of MF or SS and may be the presenting feature [1].

### Staging and prognosis

For MF/SS two staging systems are in regular use, including the TNMB (primary tumor, regional nodes, metastasis, blood) system,

revised in 2007 [5], and a clinical staging specifically designed for CTCL (Box 34.1) [6].

Most cases of primary CTCL are not curable. The majority of patients present with early-stage disease, and those with patches alone have a lower risk of progression than those with both patches and plaques. A recent multivariate analysis in a cohort of 1502 patients with MF or SS, using the revised TNMB classification, has identified risk factors for progression and survival and helps to define distinct risk groups, particularly for early-stage patients [7]. Male gender and age >60 are key risk factors. In early-stage disease, the presence of plaques, folliculotropic disease, and palpable or histologically confirmed dermatopathic lymph nodes are also poor prognostic factors [7]. The lymph-node status and tumor burden within peripheral blood determine the prognosis in SS [6,8]. Multivariate analysis indicates that an initial complete response (CR) to various therapies is an independent favorable prognostic feature, particularly in early stages of disease [9–12].

Table 34.1 summarizes actuarial survival data for MF [3,7,10–14]. Patients with early (stage IA) MF are unlikely to die of their disease; however, the prognosis of stage IB disease is more variable and partly determined by age, gender, the presence of folliculotropism, and the presence of an identical peripheral blood T-cell clone in the skin and blood.

Although the prognosis in stage IB patients is worse, there is a marked variation, and this probably reflects its heterogeneous nature, both in terms of tumor burden and biology [3,10].

The survival data for patients with erythrodermic MF but no evidence of lymph-node or peripheral blood involvement (stage III) are similar to those for stage IIB disease [3,11,14]. In contrast, the overall survival and disease-specific survival rates at 5 and 10 years for stages IVA and IVB patients is poor [7,10,13,14].

Other clinicopathological variants of CTCL are generally associated with an excellent long-term prognosis (100% 5-year survival in lymphomatoid papulosis and 90% in primary cutaneous CD30+ve anaplastic large-cell lymphoma (ALCL)), with the exception of patients with subcutaneous panniculitis-like T-cell lymphomas and primary cutaneous natural-killer (NK)-like T-cell lymphomas [1].

**Box 34.1** The recently revised TNMB (primary tumor, regional nodes, metastasis, blood) classification for MF/SS

### Skin

- T1, limited patches/plaques (<10% of total skin surface)
  - T1a – patches only; T1b – plaques ± patches
- T2, extensive patches/plaques (>10% of total skin surface)
  - T2a – patches only; T2b – plaques ± patches
- T3, tumors
- T4, erythroderma (confluent erythema >80% body surface area)

### Nodes

- N0, no clinical lymphadenopathy
- N1, clinically enlarged lymph nodes but histologically uninvolved (dermatopathic)
  - N1a – clone negative; N1b – clone positive
- N2, clinically abnormal lymph node, histologically NCI LN3
  - N2a – clone negative; N2b – clone positive
- N3, clinically abnormal lymph nodes and histologically NCI LN4, clone positive or negative
- Nx, clinically abnormal lymph nodes without histologic confirmation

### Visceral

- M0, no visceral involvement
- M1, visceral involvement (organ should be specified)

### Blood

- B0, no peripheral blood Sézary cells (<5%)
  - B0a – clone negative; B0b – clone positive
- B1, low blood tumour burden: >5% of total lymphocyte count Sézary cells but does not meet criteria of B2
- B2, high blood tumor burden:  $\geq 1000/\mu\text{l}$  Sézary cells with positive clone or  $\text{CD4/CD8} \geq 10$ ,  $\text{CD4+CD7}^-$  cells  $\geq 40\%$  or  $\text{CD4+CD26}^-$  cells  $\geq 30\%$

### Clinical staging system for MF or SS [6]

Stage	T	N	M	B
IA	T1	N0	M0	B0,1
IB	T2	N0	M0	B0,1
IIA	T1–2	N1,2, X	M0	B0,1
IIB	T3	N0–2, X	M0	B0,1
IIIA	T4	N0–2, X	M0	B0
IIIB	T4	N0–2, X	M0	B1
IVA1	T1–4	N0–2, X	M0	B2
IVA2	T1–4	N3	M0	B0–2
IVB	T1–4	N0–3, X	M1	B0–2

## Diagnostic tests

The diagnosis of different variants of primary CTCL is based on careful assessment of the clinical and histopathological features. Repeated biopsies may be required to establish the diagnosis, and clinicopathological correlation is essential. Immunophenotypic studies are required to identify different CTCL variants, and analysis of T-cell receptor genes in DNA extracted from skin biopsies can identify a T-cell clone, which helps to confirm the diagnosis. However, T-cell clones are not always detected in early stages of MF

because of a lack of sensitivity. Investigations – including a computed tomography (CT) scan of the chest, abdomen, and pelvis to exclude systemic involvement and assessment of peripheral blood for Sézary cells and lymphocyte subsets – are indicated in all patients, with the exception of those with early stages of MF (IA/IB) and lymphomatoid papulosis [15]. Bone-marrow aspirate/trephine biopsies are indicated in CTCL variants, but rarely in MF and SS.

## Aims of treatment

The aim of treatment is to induce complete or partial remission of disease and to prolong the disease-free survival and overall survival, while maintaining the patient's quality of life (Table 34.2).

## Clinical endpoints and response criteria

Historically, most trials in CTCL have been retrospective reports of case studies or phase II trials with no standardized definition of endpoints or response criteria. Most studies have reported responses based on skin disease alone, and assessments have been of variable quality with CR defined as complete resolution of clinically apparent disease for at least 4–6 weeks. Partial response (PR) is usually defined as >50% reduction of clinical disease or tumor burden, although some studies have defined this as >25% reduction in tumor burden. Stable disease (SD) is usually defined as <50% improvement, and progressive disease (PD) as >25% increase in tumor burden. For most studies PD has been defined as deterioration in the clinical stage of the disease. A quality-of-life assessment for CTCL has been published, although this has rarely been assessed in studies [16].

In 2011, the ISCL–EORTC published consensus criteria for disease endpoints and assessment tools for MF/SS, using a global scoring system, based on response in all tumor compartments. This should be used in all clinical trials, but also adopted for all patients to help accurately assess tumor burden and response to therapy [17].

- There should be accurate definitions of patches, plaques, and tumors.
- Histopathological diagnosis should be confirmed by a pathologist with expertise in cutaneous lymphoma.
- Assessment of skin involvement should be performed using the modified severity weighted assessment tool (mSWAT). This enables direct assessment of body surface area of each type of MF or SS lesion in each of the 12 areas of the body, multiplying the sum of the body surface area of each lesion by a weighting factor (patch  $\times 1$ , plaque  $\times 2$ , tumor  $\times 4$ ) [18,19].
- Assessment of lymph node and visceral involvement by staging CT scans and lymph node biopsy.
- Assessment of blood involvement with Sézary count and lymphocyte subsets.
- Establishment of molecular remission using T-cell receptor gene analysis of skin and peripheral blood.
- Quality-of-life assessment, including quality-of-life scores and assessment of itch.

## Methods of search

Systematic reviews, controlled clinical trials, and clinical trials were located by searching the Cochrane Library (1999–2012) and Medline (1985–2012). Because of a limited number of randomized clinical trials (RCTs) and the overall low incidence of CTCL, some small studies are included, and the limitations of such studies are discussed.

		31	3						Kim <i>et al.</i> 1999 [12]	176	8

All overall survival (OS) curves were calculated using the Kaplan–Meier method.

<sup>a</sup>In the study by Doorn *et al.* [10], the presence of follicular mucinosis was an independent poor prognostic feature possibly related to depth of infiltrate in patients with stage IB disease (disease-free survival of 81% and 36% and OS of 75% and 21% at 5 years and 10 years, respectively). A lack of a CR to initial therapy was also associated with a poor outcome ( $P < 0.001$ ) in a multivariate analysis as well as increasing clinical stage and the presence of extracutaneous disease. A different staging system was used in this study but the staging has been altered to be consistent. Only three patients had stage IVB disease and only 18 patients each had stage IIA and IVA disease. Therefore, the results for these stages must be interpreted cautiously.

<sup>b</sup>In the study by Zackheim *et al.* [3], black patients had a relatively more advanced stage of disease than white patients. The TNM classification was used in this study. Lymph node stage had an unfavorable impact on survival but this trend did not reach significance for *each individual* T stage because of a lack of sufficient power (an estimated 1700 subjects required) and IIA/IVA patients were not designated separately. Similar considerations apply to peripheral blood involvement. Similar outcomes for patients with stage IIB (T3) and III (T4) disease are consistent with other studies, but this might reflect a lack of lymph node staging data included in this study.

<sup>c</sup>The 1996 study by Kim *et al.* [11] primarily included data on 122 patients with stage IA disease, but survival data on 556 patients with all stages were also included to give the values in parentheses. The free from relapse (FFR) data at 5 and 10 years are confusing because the text states that the FFR at 10 years was 25% but the figure indicates that it remains at approximately 50%, as for FFR at 5 years. The median survival for stage IA patients was not reached at 32.5 years. NR, not reached.

<sup>d</sup>In the 1999 study by Kim *et al.* [12], OS at 20 years for stage IB and IIA patients was 27%. DSS was better for patients <58 years of age ( $P < 0.03$ ). In 23 of the 56 patients with palpable lymphadenopathy, no histological assessment was made and these patients were assumed to have reactive/dermatopathic nodes (IIA). This might account for the lack of difference in OS at 5 years between stage IB and IIA patients, although there appears to be a difference in OS at 10 years.

<sup>e</sup>In the 1995 study by Kim *et al.* [14], the OS and median survival data were calculated from the date of initial treatment, which was usually within 3 months of diagnosis. This study also stratified patients into three groups according to the presence of none, one, or two or three poor prognostic parameters; namely: age at presentation (>65 years), the presence of clinical adenopathy, and B1 stage, producing varied median survivals of 10.2 years (no factors), 3.7 years (one factor), and 1.5 years (two or three factors);  $P < 0.005$ .

<sup>f</sup>The study by Coninck *et al.* [13] included 112 patients with extracutaneous disease at presentation or with progression and 434 patients with only cutaneous disease, giving the 546 patients listed in the table for median survival and disease progression.

<sup>g</sup>The study by Agar *et al.* [7] studied the largest cohort of patients and was the first to validate the recent International Society for Cutaneous Lymphomas (ISCL)–European Organisation for the Research and Treatment of Cancer (EORTC) staging proposal

**Table 34.2** Treatment of MF or SS.

Stage	First-line treatment	Second-line treatment	Experimental	Not suitable
IA	SDT or no therapy	SDT or no therapy	Bexarotene gel 5% imiquimod cream	Chemotherapy
IB	SDT	Interferon alpha + PUVA, bexarotene, TSEB, HDACi <sup>a</sup> (clinical trial)	Denileukin diftitox, antibody therapies	Chemotherapy
IIA	SDT (clinical trial)	Interferon alpha + PUVA, bexarotene, TSEB (clinical trial)	Denileukin diftitox, antibody therapies	Chemotherapy
IIB	Radiotherapy or TSEB therapy, chemotherapy (Clinical Trial)	Interferon alpha, denileukin diftitox, <sup>a</sup> bexarotene, HDACi (clinical trial)	AHSCT, antibody therapies	
III	PUVA ± interferon alpha, ECP ± interferon alpha, ± bexarotene methotrexate (clinical trial)	TSEB, denileukin diftitox, <sup>a</sup> HDACi, <sup>a</sup> chemotherapy, alemtuzumab (clinical trial)	AHSCT, antibody therapies	
IVA	Radiotherapy or TSEB therapy, chemotherapy (clinical trial)	Interferon alpha, denileukin diftitox, <sup>a</sup> alemtuzumab, bexarotene HDACi <sup>a</sup> (clinical trial)	AHSCT, antibody therapies	
IVB	Radiotherapy, chemotherapy (clinical trial)	Palliative therapy (clinical trial)	AHSCT	

HDACi, histone deacetylase inhibitor; ECP, extracorporeal photopheresis; AHSCT, allogeneic hematopoietic stem cell transplant; PUVA, psoralen + ultraviolet A; SDT, skin-directed therapy including topical emollients, steroids, mechlorethamine, carmustine, bexarotene gel, UVB/PUVA, superficial radiotherapy; TSEB, total skin electron beam. Antibody therapies – other than alemtuzumab.

Stage III includes Sézary syndrome, although some cases of Sézary syndrome will be stage IVA. ECP is ideal for patients with peripheral blood involvement.

<sup>a</sup>Not yet licensed in Europe.

## Questions

### What are the effects of topical therapy in mycosis fungoides?

#### Topical corticosteroids

##### Efficacy

No systematic reviews or RCTs were identified. One large open uncontrolled study of 79 patients with MF (stage T1/T2) who were treated with class I to III (potent/moderate potency) topical corticosteroids twice daily for 3–4 months and under occlusion showed CR in 63% and PR in 31% of stage T1 patients, and CR and PR in 25% and 57%, respectively, for patients with stage T2 [20]. CR was confirmed histologically in seven patients, but the median duration was not documented.

##### Drawbacks

Reversible depression of serum cortisol levels occurred in 13% of patients, and skin atrophy in one patient.

##### Comment

The lack of controlled studies and a short median follow up of 9 months weakens the impact of the results. No evidence of impact on disease-specific survival or overall survival was reported. However, topical corticosteroids, especially class 1 (potent) compounds, are effective at temporarily clearing patches and plaques in some patients with early-stage IA/IB MF.

#### Topical mechlorethamine (nitrogen mustard)

##### Efficacy

A randomized, controlled, observer-blinded, multicenter study involving 260 patients with stage IA–IIA disease evaluated the safety and efficacy of mechlorethamine 0.02% gel compared with ointment when used once daily for up to 12 months. Response rates were similar in both groups for the primary endpoint, composite index lesion severity assessment (58.5% versus 47.7%) and mSWAT analysis (46.9% versus 46.2%); however, time-to-response analysis showed superiority of the gel compared with the ointment formulation. Similar numbers of patients in the gel (20.3%) and ointment arms (17.3%) withdrew because of drug-related skin irritation [21].

A prospective nonrandomized study of 64 patients with early-stage MF treated with a 0.02% aqueous solution of mechlorethamine followed by betamethasone cream twice weekly for 6 months reported 58% CRs. Overall, 28% developed severe cutaneous intolerance, and relapse was observed in 46% after a mean of 7.7 months [22].

A retrospective, single-center review of 123 patients treated with whole-body once-daily application of topical mechlorethamine (10–20 mg/mL; aqueous preparation from 1968 to 1980 and ointment base from 1980 to 1985) until maximum response reported CRs of 51% in IA, 26% in IB, 0% in IIB, and 22% in stage III disease [23]. There were no differences in outcome with the aqueous or ointment base. Fifty patients had received total skin electron beam (TSEB) therapy before topical mechlorethamine; 56% of patients who achieved CR relapsed despite maintenance treatment for 1–2 years [23].

A study of 117 patients reported a CR of 76% with stage I, 45% with stage II, and 49% with stage III disease within 2 years of therapy (median response duration 45 months) [24]. Patients were allowed local radiotherapy for tumors and were not excluded as responders. The overall 5-year survival was 89%.

In a retrospective review, 331 patients (1968–1982) were treated with topical mechlorethamine daily and with maintenance therapy daily or alternate days for at least 3 years for those with a CR. A CR lasting 4–14 years was observed in 20%, but only in those with stage IA–IB [25]. However, patients were allowed other therapies, including radiotherapy, TSEB therapy, phototherapy, and methotrexate to achieve a response. Relapse occurred in only 17% of these patients within 8 years of therapy being withdrawn, suggesting that some patients with very early-stage disease may have achieved a cure. Response rates were highest in the early stages of disease (IA, 80%; IB, 68%; IIA, 61%; IIB, 49%; III, 60%; IVA, 13%; IVB, 11%). The stage-specific 5/10-year survival rates were 94/89% (IA), 85/83% (IB), 82/67% (IIA), 59/31% (IIB), 75/49% (III), 20/13% (IVA), and 11/0% (IVB) [24]. In a prospective open study, 64 patients with stage IA–IIA MF were treated with twice-weekly mechlorethamine (0.02% aqueous solution) to the whole skin surface (with the exception of the head), followed by immediate topical application of betamethasone cream for 6 months [26]. Overall, 58% achieved a CR after a mean treatment duration of  $3.6 \pm 2.5$  months (20 of 33, 61%, with stage IA; 15 of 26, 58%, with stage IB; and two of five, 40%, with stage IIA). Eighteen patients (28%) developed severe cutaneous reactions necessitating treatment withdrawal, and the CR rates were significantly lower in these patients. Relapse occurred in 17 patients (46%) after a mean duration of  $7.7 \pm 6.5$  months from CR.

A retrospective study of 203 stage I–III patients treated with topical mechlorethamine (10–20 mg/100 mL) to the whole skin surface once daily until CR, as the initial therapy, revealed an overall response (OR) rate of 83% and a CR of 50%, with a median time to response of 12 months and median time to relapse of 12 months despite maintenance therapy [27]. Responses were better for early-stage IA disease (65% CR) than for stage IB (34% CR). Only 10% of patients developed contact reactions with the ointment preparation, and only 8% developed secondary malignancies. Pediatric patients ( $n = 6$ ) were also treated, with no significant toxicity. Overall, 68% of the patients were only treated throughout the follow-up period with topical mechlorethamine, and in this group the ORs were higher (T1, 77% CR; T2, 53% CR), with relapse-free rates of 74% and 54% for T1 and 54% and 29% for T2 at 2 and 5 years, respectively.

##### Drawbacks

An irritant contact dermatitis occurs in up to 40% of patients. This is less common with the ointment (0.01–0.02%). It is carcinogenic, and secondary cutaneous malignancies have been attributed to its long-term use (8.6-fold and 1.8-fold increased risk for squamous cell carcinoma and basal cell carcinoma, respectively). Home use is acceptable, with patients applying topical treatment overnight; however, partners should avoid contact, especially if pregnant. Appropriate protection for staff members applying topical therapy in the hospital setting is required, although no toxic effects have been reported [28].

##### Comments

Mechlorethamine is an effective topical therapy for early-stage (patches/thin plaques) MF. However, most studies are retrospective and confounded by the use of other therapeutic modalities. Duration of response varies, and the efficacy of maintenance therapy and whole-body application remains unclear, but some patients with stage IA disease may appear to be cured. The survival data reported for topical mechlorethamine are similar to those for

patients with early-stage disease (Table 34.1). Almost all patients with stage IA MF have a normal life expectancy, and so controlled trials are required.

### Topical carmustine

#### Efficacy

No RCTs were identified. A retrospective review of therapy in 143 patients revealed CRs in 86% of stage IA, 47% of stage IB, 55% of stage IIA, 17% of stage IIB, 21% of stage III, and 0% of stage IV patients [29]. Median time to CR was 11.5 weeks. Alternate day or daily treatment with 10 mg 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU) in dilute (95%) alcohol (60 mL) or 20–40% BCNU ointment can be used.

#### Drawbacks

Contact hypersensitivity is uncommon (10%), but bone-marrow suppression is common (30%). Total doses should not exceed 600 mg per course, and repeated courses may be required. Maintenance therapy should be avoided. The ointment is more stable than the alcohol solution.

#### Comments

Limited data suggest similar efficacy to mechlorethamine, but it is more extensively absorbed and therefore has a significant risk of bone-marrow suppression. It may help in patients with early-stage disease that show an irritant or allergic contact reaction to mechlorethamine. Comparative trials are needed.

### Topical retinoids

#### Efficacy

No RCTs were found. A prospective phase I/II open study of 0.1–1% bexarotene gel as incremental doses in 67 patients with stage IA/IB/IIA disease (initially alternate-day treatment, increasing to a maximum of four times daily if tolerated) showed a response rate of 63%, with 21% of patients showing a CR [30]. The median time to response and the duration of the response were 20 weeks and 99 weeks, respectively.

#### Drawbacks

Mild/moderate pruritus, burning pain, and rash (12% irritant contact dermatitis) were common.

#### Comment

The lack of a placebo control makes interpretation difficult. It is not licensed in Europe but has been approved by the United States Food and Drug Administration (FDA) as 1% Targretin gel for the treatment of patients with stage IA/IB disease. Further controlled studies are required.

### Topical peldesine (BCX-34)

Peldesine is an inhibitor of purine nucleoside phosphorylase, an enzyme involved in purine degradation within lymphocytes.

#### Efficacy

One RCT has compared topical application of peldesine twice daily to the entire skin surface for 24 weeks with a placebo (vehicle control) in 90 patients with stage IA/IB MF [31]. A PR or CR occurred in 28% of patients treated with peldesine and 24% of patients treated with placebo ( $P = 0.677$ ).

### Drawbacks

A minority of patients noted minor pruritus and rash.

#### Comment

Although no significant efficacy is apparent, the results indicate a high placebo therapeutic response (mostly PR), which should be considered when interpreting the efficacy of different topical therapies in early-stage MF. Data on endpoints and freedom from relapse are lacking.

### Other topical therapies

#### Efficacy

A pilot study of four patients comparing imiquimod 5% cream with placebo for 16 weeks showed no clearance (defined as clearance of at least 90% of lesion) and no improvement (improvement of at least 50% of lesion size or surface change) with either imiquimod or placebo. The only adverse effect was mild lesional irritation [32]. An open-label, pilot study of six patients with stage IA–IIB disease showed complete histological clearance of index lesions in three of six patients treated with imiquimod 5% cream three times per week for 12 weeks. Clinical response was observed in two of four lesions treated in a fourth patient [33]. A study of eight patients (four MF, one ALCL) demonstrated CR of lesions in two of four MF patients (both stage IA) and in the patient with ALCL [34]. A further report suggests a CR to 5% imiquimod cream in comparison with placebo in one patient with stage IA disease after daily application to specific lesions for 4 months; response was assessed clinically and with posttreatment biopsies [35].

There is one report of six patients with early-stage CTCL that were treated with topical 5-fluorouracil cream for between 3 and 18 months. All responded (4/6 CR, 2/6 PR), suggesting that it may have efficacy in early stages of MF [36]. Tolerance to treatment was good, with only mild skin irritation.

Topical photodynamic therapy with 5-aminolevulinic acid (5-ALA) and 100 J/cm<sup>2</sup> red light has been reported to be effective in isolated cases and small case series for patches and plaques, with clinical and/or histological clearance in 50–100% of cases [37,38]. A phase II placebo controlled study using the photodynamic agent Hypericin in combination with visible light in patients with stable patch or plaque-stage disease resulted in a significant improvement in the majority of patients with CTCL after 6 weeks of twice-weekly therapy, whereas the placebo arm showed no response ( $P \leq 0.028$ ) [39].

The excimer laser, which emits monochromatic light in the UV range at a wavelength of 308 nm, has also shown CR of individual lesions in patients with stage IA disease in small case series [40,41].

#### Drawbacks

These topical therapies can only be used for limited areas, which is a significant limitation for patients with widespread cutaneous disease.

#### Comments

Apart from two small placebo-controlled studies [32,39], the other studies are based on limited case reports. There needs to be comparative studies with other topical therapies and radiotherapy to justify their use in CTCL. Until there are technical developments of these topical therapies to permit application to large areas, it is unlikely that they will become a standard form of skin-directed therapy for CTCL.

## What are the effects of phototherapy in mycosis fungoides and Sézary syndrome?

### Efficacy

No RCTs were found. Broadband ultraviolet B (UVB, 290–320 nm) phototherapy with maintenance therapy produced a CR in 83% of 35 patients with early-stage disease (IA/IB), with a median response time of 5 months and a median response duration of 22 months [42].

Narrowband UVB (TL-01; 311–313 nm) also produced a CR in six of eight patients with stage IA disease, with a mean duration of response of 20 months [43].

A retrospective study of 24 patients with stage IA/IB disease and patches only showed CRs in 13 (54%) and PRs in seven (29%), with a histological response confirmed in nine of 10 patients and a mean time to relapse of 12.5 weeks [44].

A retrospective study of 114 patients (19 treated with narrowband UVB, 95 with psoralen+UVA (PUVA)) showed that narrowband UVB was as effective as PUVA (CR 63% compared with 62% for PUVA) for early-stage MF, with no difference in time to relapse [45].

High-dose ultraviolet A1 (UVA1) phototherapy (340–400 nm; 100 J/cm<sup>2</sup>) on a 5-day per week basis was used in 13 patients until maximal response. Eleven patients showed a CR (mean number of sessions 22; cumulative dose 2149 J/cm<sup>2</sup>) and seven remained in CR after a mean follow-up period of 7.2 months [46].

### Drawbacks

UV-induced erythema/pruritus may occur. High cumulative doses of UVA contribute to an increased risk of nonmelanoma skin cancer.

### Comments

UVB phototherapy is an effective short-term therapy for patches and thin plaques, but the duration of disease-free remission varies and the treatment probably does not affect long-term survival rates. UVA1 penetrates more deeply than UVB and PUVA, but the clinical relevance has not yet been established. No adequate comparative studies between different forms of phototherapy and PUVA have been published.

## Psoralen+ultraviolet A photochemotherapy

### Efficacy

No RCTs were found. An open study of 82 patients treated with PUVA and followed for up to 15 years reported an overall CR of 65% (79% IA, 59% IB, 83% IIA) and mean cumulative doses of 134 J/cm<sup>2</sup> (IA), 140 J/cm<sup>2</sup> (IB), and 240 J/cm<sup>2</sup> (IIA), with a median time to CR of 3 months [47]; 67% of stage IA, 41% of stage IB, and 67% of stage IIA patients were free of disease at 2 years, but maintenance PUVA was given to most patients [46]. Survival rates at 5 and 10 years were 89% for stage IA, 78% for stage IB, and – surprisingly – 100% for stage IIA.

An open study of PUVA in 82 patients with CTCL showed a CR in 62% of patients, with an 88% CR in stage IA (mean cumulative dose 160 J/cm<sup>2</sup>), 52% in stage IB (498 J/cm<sup>2</sup>), and 46% in stage III disease (178 J/cm<sup>2</sup>). No responses were seen in stage IIB patients. The maximum duration of response was 68 months; 38% of the complete responders relapsed despite maintenance PUVA [48].

A further open study has shown that 56% of stage IA and 39% of stage IB patients with a CR had no recurrence of CTCL during a maximum period of 44 months' follow-up, despite no maintenance

therapy [49]. Data from a prospective cohort study suggests that maintenance therapy does not prevent future relapse in MF. A history of previous relapse was most strongly associated with future relapse [50].

A retrospective study of the long-term outcome following CR from PUVA monotherapy at a single institution, in 66 patients with stage IA and IB/IIA disease, reported that 50% of patients ( $n = 33$ ) maintained a CR after a median follow-up of 84 months, while 50% experienced a relapse, with a median disease-free interval of 39 months [51]. Maintenance PUVA was given to almost all patients with a CR/PR. The only significant difference between the two groups was a higher cumulative UVA dose and the number of PUVA sessions in those achieving a CR. There was no significant difference in the overall survival rate for the nonrelapse and relapse cohorts.

### Drawbacks

Adverse effects include nausea, phototoxic reactions, and skin carcinogenesis. The risk of nonmelanoma skin cancer is related to the cumulative dose and total number of sessions.

### Comments

Despite the lack of controlled trials, PUVA remains one of the most useful skin-directed therapies for early stages of MF. RCTs comparing PUVA with TL-01 and topical mechlorethamine would be helpful in early-stage disease (IA/IB). The role of maintenance therapy is unclear, but high cumulative doses entail a significant risk of squamous cell carcinoma. There appears to be little difference in disease-free survival and overall survival rates in patients treated with topical chemotherapy, phototherapy, and TSEB therapy, but it is difficult to compare without RCTs.

## Combination regimens involving photochemotherapy

### Efficacy

An RCT compared PUVA two to five times per week, plus interferon alpha, 9 MU three times per week, with interferon alpha plus acitretin, 25–50 mg/day, in 98 patients (maximum duration of treatment 48 weeks) [52]. In 82 patients with stage I/II disease, CR rates were 70% in the PUVA/interferon group in comparison with 38% in the interferon and acitretin group ( $P < 0.05$ ). Responses were assessed by clinical observation only. Time to response was 18.6 weeks in the PUVA/interferon group, compared with 21.8 weeks in the interferon and acitretin group ( $P = 0.026$ ). No data on response duration were reported. The total cumulative doses of interferon alpha were similar in both groups.

An open study of 69 patients compared PUVA and acitretin with PUVA alone in MF [52]. The cumulative dose of PUVA needed to achieve a CR was lower in the combined-treatment group, although the overall CR was similar in the two groups (73% and 72%, respectively). No data on response duration were documented [53].

Phase I and II studies of PUVA (three times weekly) combined with variable doses of interferon alpha (maximum tolerated dose of 12 MU/m<sup>2</sup> three times per week) in 39 patients with MF and SS reported an OR of 90%, (62% CR, 28% PR); 79% of stage IB, 80% of IIA, 33% of stage IIB, 63% of stage III patients, and 40% of stage IVA patients obtained a CR [54]. PUVA was continued as a maintenance therapy indefinitely, while interferon alpha was continued for 2 years, until disease progression or withdrawal due to adverse effects. The median response duration was 28 months and median survival 62 months [54].

A prospective phase II study of PUVA (three times weekly with maintenance PUVA after CR) combined with interferon alpha (escalating dose schedule of 3–12 MU three times weekly according to tolerability) in 63 patients with all stages (37 stage IB, 12 stage III) for 1 year reported a CR of 75%, with a median response duration of 32 months [55]. The overall 5-year disease-free survival rate was 75%. A second prospective phase II study assessing the combination of interferon alpha (6–18 MU/week) and PUVA in 89 patients with stage IA–IIA MF treated for 14 months showed an 84% CR, with sustained remission in 20% [56].

A phase III multicenter randomized trial of PUVA versus PUVA plus bexarotene in 93 patients (87 started treatment, 41 PUVA, 46 PUVA plus bexarotene) showed similar ORs of 71% in the PUVA arm and 77% in the combination arm. There was no significant difference in response duration; however, there was a trend towards fewer PUVA sessions and lower UVA dose required to achieve CR in the combination arm [57].

In another study of 14 patients with relapsed or refractory MF who received a combination of bexarotene plus PUVA three times per week there was an OR of 67% in the nine patients that completed the treatment course; five withdrew because of hyperlipidemia [58].

### Drawbacks

These were, as for PUVA, interferon alpha, bexarotene, and acitretin alone. In the RCT comparing PUVA and interferon alpha with acitretin and interferon alpha [52], similar rates of mild/moderate adverse effects were noted in both groups, but more patients discontinued treatment in the interferon/acitretin group because of adverse effects.

### Comments

The RCT comparing PUVA and interferon alpha with interferon alpha and acitretin shows that PUVA and interferon alpha is more effective than interferon alpha and acitretin in early-stage I/II disease. Weaknesses of this study include the lack of a validated scoring system to assess tumor burden and a lack of evidence that outcome was assessed blind to allocation status. The trial comparing PUVA alone with PUVA plus acitretin [53] suggests a reduction in the mean cumulative dose of PUVA to CR, but there is no evidence for increased overall efficacy in the retinoid–PUVA group. The combination of interferon alpha and PUVA appears to be highly effective in all stages of CTCL. It should be noted, however, that the overall remission rate may be similar to that with PUVA alone, and randomized data for duration of remission and cumulative UVA dose are urgently required.

The RCT comparing PUVA with PUVA plus bexarotene used a validated scoring system to assess tumor burden; however, only 93 of the 145 required patients were randomized owing to low accrual and, therefore, the study lacks power [57].

## What are the effects of immunotherapy in mycosis fungoides/Sézary syndrome?

### Interferon alpha

#### Efficacy

No RCTs have been reported, except as combination therapy (see above).

Table 34.3 summarizes the studies of interferon alpha in the treatment of MF/SS.

A small retrospective study of 17 patients with stage IA–IV MF comparing pegylated interferon alpha-2b plus PUVA with standard

**Table 34.3** Comparison of studies of interferon alpha in CTCL.

Study design	No. of patients	Stage of disease	Interferon alpha dose	Overall response (%)	CR (%)	Median response duration (months)	Disease-free survival rate (%)	Comments
RCT PUVA plus IFN versus IFN plus acitretin [52]	98	I–IV (82 stage I/II)	9 MU 3×/week (plus either PUVA 2–5×/week or acitretin 25–50 mg/day) for maximum 48 weeks		IFN/PUVA 70 IFN/acitretin 38 (in 82 patients with Stage I/II disease ( $P < 0.05$ ))	Not reported	—	Time to response between the 2 groups not significant (18.6 versus 21.8 weeks) Total cumulative doses of IFN similar in both groups
Open [59]	20	IB–III	50 MU/m <sup>2</sup> 3×/week for 3 months	45%		5	—	All heavily pretreated
Nonrandomized [60]	22	IA–IVA	Escalating schedule to 36 MU/day versus 3 MU/day for 10 weeks	64% (78 versus 37)	27	—	—	Objective response greater in those treated with dose-escalating schedule, but numbers too small for statistical comparison
Open [61]	43	I–IV	3–18 MU daily (escalating dose)	74% Stage I/II 88 Stage III/IV 63	26	—	21 (at 55 months)	Responses more common if no prior treatment
Phase II [62]	24	IVA/B	High dose (mean 65.5 MU/m <sup>2</sup> per week) on days 1–5 every 3 weeks	29%	4% (1 of 24)	—	—	Dose reductions necessary. No improved response on dose escalation
Open [63]	45	All stages (13 of 45 SS)	6–9 MU daily for 12 months. Acitretin 0.5 mg/kg per day added after 3 months if no response	62% after 12 months (including 11 patients on combined therapy)	—	—	—	Not possible to exclude possibility that response in interferon alpha nonresponder group due to delayed efficacy from continued interferon alpha

IFN, interferon alpha; PUVA, psoralen+ultraviolet A; RCT, randomized controlled trial; SS, Sézary syndrome.

interferon alpha-2b plus PUVA showed a higher overall response rate with less constitutional side effects in the pegylated interferon alpha-2b group. However, there was a higher rate of myelosuppression and liver toxicity [64].

### Drawbacks

The dose-limiting toxicity includes reversible hematological abnormalities, hepatitis, weight loss, headache, depression, and flu-like symptoms consisting of fever, myalgia, lethargy, and anorexia.

### Comments

The clinical efficacy in all stages of CTCL is supported by the CRs seen in uncontrolled studies. It appears that higher doses are more effective, but dose-limiting toxicity is a problem. Larger studies are required to confirm whether pegylated interferon alpha is appropriate in MF. Questions remain about the effect on disease-free survival and overall survival and the role of combined therapy with PUVA.

## Extracorporeal photopheresis

### Efficacy

No RCTs were reported. Response rates to extracorporeal photopheresis (ECP) vary widely between different study groups. A recent systematic review of ECP treatment in over 650 patients from 30 published studies showed a mean response rate of 63% (range 43–100%) [65]. Responses were assessed mostly using a scoring system similar to that devised for the original study [66] and were higher in those with erythrodermic CTCL [66–69]. CRs were recorded in 27 studies involving 527 patients with a mean CR of 20% [65]. The differences in response rates between centers may relate to different patient selection for treatment with ECP, such as the presence of a peripheral T-cell clone, stage of disease, prior treatment, ECP protocol, duration of ECP, and definition of response. Survival data have been reported in erythrodermic disease, with median survivals of 39–100 months from diagnosis [68–71].

There have been numerous small case series reported of stage III patients treated with combinations of ECP, interferon alpha and/or retinoids, including bexarotene, which suggest that combination therapy can be highly effective as both clinical and molecular remissions have been documented [65,70,72–79].

A randomized crossover study comparing ECP with PUVA in patients with nonerythrodermic (stage IB–IIA) MF has shown no clinical efficacy for ECP in early stages of the disease in comparison with PUVA [80].

In contrast, a multicenter, prospective study of 19 patients all with early-stage MF (three stage IA, 14 stage IB, and two stage IIA) showed an OR of 42% (seven PR, one CR), with a median of 12 ECP sessions (range, 3–32) given over a median of 12 months (3–32 months) and with an overall response duration of 6.5 months (range 1–48 months). Quality-of-life questionnaires also showed an improvement in emotional scores [81].

### Drawbacks

ECP is well tolerated. Mild lymphopenia and anemia can occur with long-term therapy. High cost and lack of availability mean that ECP will remain confined to specialist centers.

### Comments

Controlled trials are required to compare ECP with standard single-agent chemotherapy regimens in erythrodermic disease and spe-

cifically in SS. Some previous studies have not clearly defined their diagnostic criteria for erythrodermic CTCL, and others have included patients with nonerythrodermic disease. Combination therapy with ECP and interferon alpha is frequently used, but existing studies do not exclude a beneficial response to interferon alpha alone.

Studies suggest that ECP requires a minimum tumor burden within peripheral blood [82], and the only RCT of ECP in nonerythrodermic, early-stage disease suggests that it is not effective [80].

## What are the effects of systemic retinoids in mycosis fungoides and Sézary syndrome?

### Etretinate, acitretin, and isotretinoin

#### Efficacy

A systematic review (1988–1994) of open studies of oral retinoids in CTCL (MF and SS) showed a mean OR of 58% and a CR of 19%, with a median duration of response of 3–13 months [83].

A nonrandomized study of 68 patients with various stages of MF/SS compared isotretinoin with etretinate and found similar efficacy and toxicity (isotretinoin: CR 21%, PR 38%; etretinate: CR 21%, PR 46%) [84]. A phase II study of isotretinoin in 25 patients with MF (IB–III) showed an OR of 44%, with three patients achieving a CR, and a median response duration of 8 months using high doses (2 mg/kg per day) [85].

An RCT comparing PUVA and interferon alpha with PUVA and acitretin showed a significantly better response rate for PUVA and interferon alpha [52] (see above).

### Drawbacks

Adverse events include mucocutaneous erosions and xerosis, hyperlipidemia, hepatotoxicity, and teratogenicity.

### Comments

Acitretin and etretinate have some efficacy in the early stages of disease, but are no better and probably less effective than PUVA and interferon alpha.

## Bexarotene

### Efficacy

No RCTs were found. A phase II open trial compared two doses (6.5 mg/m<sup>2</sup> per day and 650 mg/m<sup>2</sup> per day) of oral bexarotene in 58 patients with refractory stage IA–IIA CTCL [86]. The optimal dose was 300 mg/m<sup>2</sup> per day in terms of response and tolerability. ORs of 20%, 54%, and 67% were noted at the 6.5 mg/m<sup>2</sup> per day, 300 mg/m<sup>2</sup> per day, and 650 mg/m<sup>2</sup> per day doses, respectively. Rates of disease progression were 47%, 21%, and 13%, respectively. Median duration of response at the highest dose level was 516 days. In late stages of disease (stage IIB–IVB), ORs of 45% (at 300 mg/m<sup>2</sup> per day) and 55% (at doses >300 mg/m<sup>2</sup> per day) were reported, with a relapse rate of 36% and a projected median duration of response of 299 days [87].

Another study reported a PR of only 14% after 8 weeks (increased to 22% when interferon alpha was added for a further 8 weeks) [88]. However, the median time to response with bexarotene monotherapy is 180 days, suggesting that a longer initial period on bexarotene alone would have achieved a greater response rate [88].

A retrospective review of 66 patients (19, stage IB–IIA; 47, stage IIB–IVB) treated with bexarotene, either alone or with one or more additional adjuvant therapies, showed that, of the 52 patients that completed over 1 month of therapy, 9% had a CR, 35% PR, 23%

SD, and 12% PD. The median time to maximal response was 3 months and the median response duration was 8 months. Responses were seen in 26% of early disease and 51% of advanced disease. The weakness of this study was that PRs were not graded and included if there was any improvement in skin, blood, or lymph node disease [89].

### **Drawbacks**

Reversible adverse effects included hyperlipidemia, central hypothyroidism, leukopenia, headache, and asthenia, as well as other retinoid adverse effects.

### **Comments**

These studies suggest a therapeutic efficacy for bexarotene in all stages of CTCL, but comparisons with other therapies and data on effects on disease-free survival and overall survival in later stages of disease are required. Combination with other therapies, including phototherapy and interferon alpha, appears to be well tolerated [56,90,91]. Although the combination of PUVA and bexarotene shows a similar OR to PUVA alone, there is a trend towards fewer PUVA sessions and a lower UVA dose in order to obtain a CR [57].

## **What are the effects of antibody and toxin therapies in mycosis fungoides and Sézary syndrome?**

### **Anti-CD4 monoclonal antibodies**

#### **Efficacy**

In a phase I/II trial, seven patients with MF were treated with a chimeric (murine/human) anti-CD4 monoclonal antibody with successive increasing doses (10, 20, 40 and 80 mg) twice weekly for 3 weeks. All patients showed short-lived clinical responses (one CR, two PR) with a median duration of 2 weeks [92].

A subsequent study from the same group showed a PR in seven of eight patients given higher doses (50–200 mg), with a median freedom from progression of 28 weeks [93].

### **Drawbacks**

Treatment was well tolerated, with no acute toxicity. There is a marked but temporary suppression of T-cell proliferative responses to phytohemagglutinin. There is no documented depletion of CD4 counts. The immunogenicity of the antibody is unclear.

### **Zanolimumab**

Zanolimumab is a fully human anti-CD4 monoclonal antibody specific for the CD4 receptor expressed on T-lymphocytes. In two phase II prospective, multicenter, open-label, uncontrolled studies in refractory CD4+ve CTCL (38 MF, nine SS), 17 weekly infusions were given at two treatment doses (280 mg/560 mg in early-stage disease, 280 mg/980 mg in advanced disease). An OR of 56% was obtained in the high-dose groups (15% in the 280 mg group) with a median response duration of 81 weeks. The main adverse effect was dermatitis [94].

### **Comments**

A further pivotal study is underway in the USA.

### **Alemtuzumab (Campath-1H)**

#### **Efficacy**

There are no RCTs. Phase II trials of alemtuzumab (a humanized anti-CD52 monoclonal antibody) in small cohorts of patients with advanced MF or SS have shown encouraging overall response rates

[95–103]. Over 100 patients have been treated in 10 reported studies. ORs have ranged from 37 to 100% and are typically short-lived. Responses are best in erythrodermic disease, where symptomatic benefit is often dramatic. In the majority of the studies alemtuzumab has been administered intravenously at the standard dose of 30 mg three times per week.

Table 34.4 summarizes the findings in six trials.

### **Drawbacks**

Severe neutropenia and opportunistic infections are common, including cytomegalovirus reactivation. There have been reports of possible cardiac toxicity [98], but in most reports the safety profile has been acceptable, even in elderly patients [102].

### **Comments**

Alemtuzumab is a humanized anti-CD52 antibody that binds to all lymphocytes. Prolonged responses can be achieved in erythrodermic MF and SS. Reduced-dose schedules have been shown to induce a response with avoidance of life-threatening infections and a reduction in hematological toxicity.

## **Denileukin diftitox (diphtheria interleukin-2 fusion toxin) Efficacy**

Denileukin diftitox (DD) is a fusion protein in which the receptor binding domain of the diphtheria toxin has been exchanged for that of the interleukin-2 (IL-2) molecule. The diphtheria-toxin-mediated activity will predominantly only affect cells that express the IL-2 receptor. It is given intravenously on five consecutive days repeated every 21 days for up to eight cycles.

A phase III placebo-controlled trial of 144 patients (less than three prior treatments) gave an OR of 44% (10% CR, 34% PR) compared with 15.9% for the placebo group. The OR was higher in the 18 µg/kg per day group compared with the 9 µg/kg per day group (49.1% versus 37.8%). There was also a significant prolongation of progression-free survival (PFS) compared with placebo [104]. There was a significant improvement in quality of life ( $P = 0.041$ ) and pruritus severity ( $P = 0.05$ ) in responders compared with non-responders at the study endpoint. In a phase III study evaluating the safety and efficacy of DD in 20 patients who relapsed after responding to DD in the previous trial, there was an OR of 40% with a median duration of response of 274 days [105].

A phase III open uncontrolled study of DD in 71 patients with stage IB–IVA CTCL and biopsies showing >20% CD25+ve (IL-2R) lymphocytes, showed an OR of 30% (10% CR) [106]. The median duration of response was 6.9 months. No difference in response rates or duration of response was noted between 9 and 18 µg/kg per day. The development of anti-DD antibodies did not affect response rates.

An open-label study of 36 patients with low CD25 expression (<20% CD25+ve cells on skin biopsy) showed a similar OR of 30.6% (33.3% early stage, 26.7% stage IIB or greater) with a median PFS of >487 days [107].

A phase I study of combined DD (18 µg/kg per day for 3 days out of 21 days) and escalating doses of bexarotene (75–300 mg/day) in 14 patients with relapsed or refractory CTCL showed an OR of 67% (four CR, four PR) and no increased toxicity [108].

### **Drawbacks**

Adverse effects include flu-like symptoms, acute infusion-related hypersensitivity effects, a vascular leak syndrome, and transient elevations of hepatic enzymes.

**Table 34.4** Comparison of studies of alemtuzumab in CTCL.

Study design	No. of patients	Stage of disease	Alemtuzumab dose	Overall response (%)	CR (%)	Median response duration (months)	Median overall survival (months)	Comments
Open [103]	19	III–IV	Increasing doses to 30 mg intravenous 3×/week for 4 weeks followed by subcutaneous administration for 8 weeks	84	47	6	41	Heavily pretreated patients
Phase II [95]	8		30 mg intravenous 3×/week for maximum of 12 weeks	50	25	NR		High rates of infectious complications
Phase II [96]	8	Advanced/refractory	30 mg intravenous 3×/week for maximum of 12 weeks	38	0	3		Significant hematological and immunosuppressive toxicity
Phase II [97]	22	III–IV	30 mg intravenous 3×/week for maximum of 12 weeks	55	32	12		
Phase II [100]	4 with MF		Reduced dose – maximum 10 mg 3×/week for maximum 3 weeks	75	0			Hematological toxicity reduced with lower dose
Prospective [101]	14	SS (11 relapsed refractory, 3 treatment naive)	10–15 mg 3×/week	85.7	21.4	12	35	Infectious complications in 28.6% (all had 15 mg dose)

MF, mycosis fungoides; SS, Sézary syndrome; NR, not recorded.

### Comments

DD is currently not licensed for use in Europe. Recent studies have demonstrated that it is possible to retreat patients that have previously responded to DD and that responses can be obtained in those with low CD25 expression [105,107].

### What are the effects of novel agents that interfere with gene expression?

#### Histone deacetylase inhibitors

##### Efficacy

The histone deacetylase inhibitors (HDACis) vorinostat and romidepsin are novel agents that increase acetylation of histones and other proteins leading to tumor suppressor gene transcription, inhibition of tumor cell growth and apoptosis.

There are no RCT's. A nonrandomized phase II trial of vorinostat was performed at three dosing schedules. Thirty-three patients were enrolled, a PR was obtained in eight patients (median time to response 11.9 weeks, median response duration 15.1 weeks). Relief of pruritus was obtained in 45% of patients. The dosing schedule of 400 mg daily was selected as the most beneficial [109]. In a further phase IIb study of 74 patients with stage IB–IVA disease (61 with IIB or greater), OR (measured by mSWAT) was 29.7% (median time to response 56 days, median time to progression 4.9 months) [110]. Two years following enrolment, six of 74 patients remained on vorinostat (five with continued response and one with SD), providing evidence for its long-term safety and tolerability [111].

In a single-arm, phase II, open-label multinational study of intravenous romidepsin in 96 patients (71% with advanced disease) there was an OR of 34% with six CRs (38% with advanced disease, including five CRs). The median time to response was 2 months and median duration of remission was 15 months. Improvement in

pruritus was noted in 28 of 65 patients (43%), including patients with no objective clinical response [112].

In a phase II multicenter study of 71 patients (87% with advanced disease), there was an OR of 34% with four CRs. Median duration of response was 13.7 months [113].

##### Drawbacks

Adverse effects include nausea, vomiting, fatigue, thrombocytopenia, and granulocytopenia.

##### Comments

Both HDACis have FDA approval in the USA for use in patients with persistent, progressive, or recurrent disease and have failed two prior systemic therapies. They are not currently licensed in Europe but can be obtained on a compassionate basis in patients who have exhausted all other treatment options.

#### Bortezomib

##### Efficacy

A phase II trial of the proteasome inhibitor bortezomib in patients with relapsed or refractory CTCL demonstrated an OR of 67% (17% CR, 50% PR) in 12 patients (10 CTCL, two peripheral T-cell lymphoma (PTCL) with only skin involvement) [114].

##### Drawbacks

Adverse effects included neutropenia, thrombocytopenia, and sensory neuropathy.

##### Comments

Larger studies are needed in order to establish its clinical role.

## What are the effects of radiotherapy in mycosis fungoides and Sézary syndrome?

### Superficial radiotherapy

#### Efficacy

No systematic reviews or RCTs were identified. Dose–response studies have established that localized superficial radiotherapy is an effective palliative therapy for individual lesions in MF [115]. A retrospective study of palliative superficial radiotherapy used to treat 191 lesions from 20 patients with MF showed CRs of 95% for plaques and small (<3 cm) tumors and a CR of 93% for large tumors (>3 cm), irrespective of dose. However, in-field recurrences within 1–2 years were more common for lesions treated with lower doses (42% for <10 Gy, 32% for 10–20 Gy, 21% for 20–30 Gy, and 0% for >30 Gy).

In a more recent study, 31 patients with MF were treated at 82 symptomatic sites. Initially, patients were treated with 4 Gy in two fractions (17 lesions); however, 70% of the lesions failed to respond. Increasing the dose to 8 Gy in two fractions yielded a CR of 92% (60 of 65 lesions) [116].

#### Drawbacks

Superficial radiation is well tolerated. Mild local erythema and occasional erosion have been reported. Use of low-dose/energy (8 Gy in two or three daily fractions at 80–150 kV) is therapeutically effective and allows treatment of overlapping fields and lower limb sites.

#### Comments

CTCL is highly radiosensitive, and localized superficial radiotherapy is an invaluable treatment for patients with all stages of MF. Treatment should be palliative except for patients with solitary localized disease, in whom a “cure” is theoretically possible. The use of high-dose fractionation regimens for individual lesions should be avoided because the CRs are similar to those for low-dose regimens (see above) and recurrent disease adjacent to previously treated fields can be treated with overlapping fields if necessary. Treatment of disease on the lower legs can be difficult, in view of a higher risk of radiation necrosis with repeated treatments.

### Total skin electron beam therapy

#### Efficacy

A systematic review of mostly retrospective studies of TSEB therapy as monotherapy for 952 patients with all stages of CTCL has established that response is dependent on the stage of disease, skin surface dose, and energy, with CRs of 96% in stage IA/IB/IIA disease, 36% in stage IIB disease, and 60% in stage III disease [117]. Greater skin surface dose (32–36 Gy) and higher energy (4–6 MeV) were significantly associated with a higher CR; 5-year relapse-free survivals of 10–23% were noted [117].

One small RCT has compared TSEB therapy with topical mechlorethamine in 42 patients, with similar CRs and response durations in both groups in early stages of disease, but better overall responses in later stages of disease with TSEB therapy [118].

A retrospective study of TSEB therapy (median dose 32 Gy; median treatment time 21 days) as monotherapy for 45 patients with erythrodermic CTCL (stage III–IVB) showed a CR of 60% with 26% disease free at 5 years [119]. The overall median survival was 3.4 years, which was associated significantly with an absence of peripheral blood involvement (stage III disease). Higher CRs (74%) and rates of disease-free progression (36%) were noted in patients receiving a more intense regimen (32–40 Gy and 4–6 MeV).

A retrospective study of 66 CTCL patients (1978–1996) treated with 30 Gy in fewer fractions (12 fractions over 40 days) showed a CR of 65%, with PFS of 30% at 5 years and 18% at 10 years [120]. Responses, and specifically the 5-year overall survival, were highest in those with early-stage disease (79–93% for IA/IB/III compared with 44% for IIB/IVA/B).

Several reports have described multiple courses of TSEB therapy in CTCL [121,122]. A retrospective analysis of 15 patients (1968–1990) with MF who received two courses of TSEB therapy reported a mean dose of 32.6 Gy for the first course and 23.4 Gy for the second, with a mean interval of 41.3 months. The CR for the second course was lower (40% compared with 73%) with no additional toxicities [121]. A study of 14 patients reported a mean dose of 36 Gy for the first course (93% CR) and 18 Gy for the second course (86% CR) [122]. Five patients received a third course (total dose 12–30 Gy). The median duration of response was 20 months for the first course and 11.5 months for the second course. No additional toxicities were reported. In both studies, the fractionation regimens employed may have been critical for tolerability (1 Gy per day at 6 MeV over 9–12 weeks).

In a retrospective study, 141 patients received TSEB therapy with a mean total dose of 30 Gy. The OR was 94.7%. In those with T1 and T2 disease (57) the CR was 87.5% and 84.8% respectively, and 54.4% relapsed within 1 year. Eighteen received a second course; the remaining 13 patients were treated with other modalities, including topical steroids, PUVA, and topical or systemic chemotherapy. The 5-year freedom from relapse was 70% compared with 39% for the other treatment modalities combined [123].

Similar response rates and durations have been reported with lower doses of TSEB therapy. A retrospective study of 102 patients (stage T2 51, T3 29, T4 22) were treated in three different dosage groups (5 to <10 Gy, 10 to <20 Gy, and 20 to <30 Gy). The overall response (>50% improvement) was 90% in the low-dose group compared with 98% and 97% in the other two groups respectively. There was no significant difference in median PFS in the T2 and T3 patients when stratified by dose group, and PFS in each group was comparable to patients that had received the standard dose of 30–36 Gy [124].

A prospective phase II study evaluated low-dose TSEB therapy (10 Gy) in 10 patients with stage IB–IV MF (four fractions of 1 Gy weekly to a total dose of 10 Gy). The OR was 90% with a CR or very good PR (<1% skin affected) of 70% and median response duration of 5.2 months [125].

### Combination total skin electron beam therapy regimens

An RCT that included 103 CTCL patients in which TSEB therapy and multiagent chemotherapy (CAVE: cyclophosphamide, Adriamycin, vincristine, and etoposide) was compared with sequential topical therapy, including superficial radiotherapy and phototherapy, reported a higher CR in the TSEB therapy/chemotherapy group (38% compared with 18%;  $P = 0.032$ ), but after a median follow-up of 75 months, the disease-free survival and overall survival did not differ significantly [126].

A retrospective study comparing TSEB therapy (32–40 Gy) alone with TSEB therapy followed by ECP (given 2 days monthly for a median of 6 months) in 44 patients with erythrodermic MF/SS (57% stage III, 30% stage IVA, 13% stage IVB; overall, 59% had B1 hematological involvement) has reported a CR of 73% after TSEB therapy, with a 3-year disease-free survival of 49% for 17 patients who received only TSEB therapy (overall survival 63%) and 81% for 15 patients who received TSEB therapy followed by ECP (overall

survival 88%) [127]. A multivariate analysis suggested that the combination of TSEB therapy and ECP was significantly associated with a prolonged disease-free and cause-specific survival when corrected for peripheral blood involvement (B1) and stage of disease.

### Drawbacks

Adverse effects of TSEB therapy include radiation-induced secondary cutaneous malignancies, telangiectasia, pigmentation, anhidrosis, pruritus, alopecia, and xerosis.

### Comments

EORTC consensus guidelines for TSEB therapy use in CTCL have been published [128].

Although these studies are uncontrolled and mostly retrospective, response rates indicate that TSEB therapy is highly effective for CTCL. Lower doses of TSEB therapy show similar response rates, are associated with fewer side effects, and allow further treatment courses to be given at relapse.

An RCT in CTCL indicates that combined TSEB therapy and chemotherapy is no more effective than sequential skin-directed therapy. Studies of low-dose TSEB therapy alone and in combination with newer agents are ongoing.

The data on long-term disease-free survival and overall survival in erythrodermic CTCL suggest that TSEB therapy is effective, particularly if combined with ECP, but this requires confirmation in an RCT.

## What are the effects of single-agent chemotherapy in mycosis fungoides/Sézary syndrome?

### Single-agent chemotherapy regimens

#### Efficacy

No RCTs have been reported. A systematic review of uncontrolled open studies of single-agent regimens in 526 CTCL patients (1988–1994) revealed ORs of 62%, with a CR of 33% and median response durations of 3–22 months [83]. These therapies included alkylating agents (chlorambucil and cyclophosphamide), antimetabolites (methotrexate), vinca alkaloids, and topoisomerase II inhibitors.

### Drawbacks

Infection and myelosuppression are significant risks.

### Comments

The lack of controlled studies makes interpretation difficult, but single-agent regimens may have similar efficacy to combination regimens (see below) with lower toxicity and may be preferable as palliative therapy in late stages of MF and SS as durable responses and cures are rarely achieved.

### Methotrexate and trimetrexate

#### Efficacy

A retrospective report of low-dose methotrexate in 29 patients with erythrodermic CTCL (III/IVA) has shown a 41% CR, with an OR of 58% [129]. Median freedom from treatment failure was 31 months and overall survival was 8.4 years. Weekly doses ranged from 5 to 125 mg for a median duration of 23 months. Trimetrexate, a lipophilic antifolate that diffuses passively into cells and is therefore less prone to drug resistance, was assessed in an open trial of 20 patients with refractory/resistant CTCL (three ALCL, 15 MF or SS with large-cell transformation in 14, two PTCL) using a schedule

of 200 mg/m<sup>2</sup> every 14 days for up to 12 doses. There was an OR of 45% (one CR, eight PR), including two patients who had previously been resistant to methotrexate [130].

### Drawbacks

Adverse effects in the methotrexate trial included reversible abnormalities of liver function, mucositis, cutaneous erosions, reversible leukopenia and thrombocytopenia, nausea, diarrhea, and in one case pulmonary fibrosis. Trimetrexate has a similar pattern of adverse effects and appears to be well tolerated.

### Comments

Although these data are uncontrolled, the overall survival in the methotrexate study is surprisingly good. A randomized study comparing methotrexate with other single-agent chemotherapies in erythrodermic CTCL would be worthwhile. The use of trimetrexate in CTCL merits further investigation.

### Pralatrexate

Pralatrexate is emerging as a promising new agent in the treatment of CTCL.

#### Efficacy

Twelve patients with transformed MF were included in a phase II study of pralatrexate (30 mg/m<sup>2</sup> per week for 6 weeks of a 7-week cycle) in patients with PTCL. The OR was 25% [131].

In a phase II study of 29 patients with heavily pretreated CTCL (15 mg/m<sup>2</sup> per week for 3 weeks out of every 4 weeks) the median number of cycles was four and the OR was 45% (evaluated by the mSWAT tool) [132].

### Drawbacks

Adverse effects include mucositis, leukopenia, thrombocytopenia, and anemia.

### Comments

The lower dose was well tolerated, with reduction in adverse effects, including mucositis.

### Purine analogues

#### Efficacy

A systematic review of purine analogues in CTCL (1988–1994) revealed respective ORs and CRs of 41% and 6% for deoxycoformycin ( $n = 63$ ), 41% and 19% for 2-chlorodeoxyadenosine ( $n = 27$ ), and 19% and 3% for fludarabine ( $n = 31$ ) [83]. Most studies included patients with PTCLs. No comparative studies were available.

A prospective open study of deoxycoformycin at starting doses of 3.75–5.0 mg/m<sup>2</sup> per day for 3 days every 3 weeks, in 28 heavily pretreated patients, of whom 21 had CTCL (14 with SS, seven stage IIB) revealed an OR of 71%, with 25% CR and 46% PR. The response was short-lived (median duration 2 months for stage IIB, 3.5 months for SS), except in two cases of SS, with remissions for 17 and 19 months [133].

Two open studies of deoxycoformycin in patients with CTCL (27 MF and 37 SS) have shown ORs of 35–56%, with CRs from 10 to 33% and a median disease-free interval of 9 months in one of the studies [134,135]. Responses were better in SS than in MF.

Combination therapy consisting of deoxycoformycin and interferon alpha in CTCL has shown ORs and CRs of 41% and 5%, respectively [136].

A phase II trial of 2-chlorodeoxyadenosine in 21 refractory CTCL patients (MF IIB/IV and SS) revealed an OR of 28%, with a 14% CR (median duration of 4.5 months) and a 14% PR (median duration 2 months) [137].

#### **Drawbacks**

Side effects include nausea, infections (especially herpetic), CD4 lymphopenia, renal toxicity, hepatotoxicity, and myelosuppression (especially for 2-chlorodeoxyadenosine and fludarabine).

#### **Comments**

Although efficacy in CTCL is moderate, most patients were heavily pretreated and relatively chemoresistant. Patients with SS appear to respond better. Purine analogues are appropriate as monotherapy, especially in SS, but the response duration may be short. Comparative trials with other single-agent regimens in SS are required.

### **Gemcitabine**

#### **Efficacy**

A phase II prospective trial (1200 mg/m<sup>2</sup> weekly for 3 weeks each month for three cycles) in 44 previously treated patients with CTCL (30 MF stage IIB or III) reported a PR of 59% and a CR of 12%, with median durations of 10 months and 15 months, respectively [138]. A phase II prospective trial in 32 patients with either CTCL (26 MF, one SS) or PTCL (five) treated with 1200 mg/m<sup>2</sup> on days 1, 8, and 15 of a 28-day cycle for six cycles revealed seven (22%) CRs and 17 (53%) PRs, with a median duration of CR of 10 months [139].

#### **Drawbacks**

The treatment was well tolerated with only mild hematological toxicity.

#### **Comments**

Gemcitabine is a pyrimidine analogue that is well tolerated in heavily pretreated patients with advanced stages of MF. Further trials are required.

### **Doxorubicin**

#### **Efficacy**

A phase II prospective, multicenter study of pegylated liposomal doxorubicin (20 mg/m<sup>2</sup> at days 1 and 15 every 28 days for six cycles) in 40 heavily pretreated patients with stage IIB, IVA, or IVB disease showed a CR of 6.1% and a PR of 34.7% using global response criteria. However, 60.5% of patients had >50% reduction in skin manifestations. The median time to progression was 7.4 months and the median duration of response was 6 months. There were two early deaths: one from cardiovascular toxicity and another from disease progression [140].

A second multicenter, prospective study of objective response to pegylated liposomal doxorubicin (40 mg/m<sup>2</sup> once every 4 weeks for up to eight cycles) in 25 patients with stage II–IV CTCL (who had failed to respond to two previous lines of therapy or who had histologically transformed epidermotropic disease) showed an OR of 56% (five CR, nine PR). The median PFS from end of treatment was 5 months. The higher dose of 40 mg/m<sup>2</sup> did not improve efficacy but did increase toxicity [141].

An open study of pegylated liposomal doxorubicin (20 mg/m<sup>2</sup> monthly to a maximum of 400 mg or eight cycles) in 10 patients with MF, revealed a CR in six patients and a PR in two patients,

with a median response duration of 15 months [142]. A retrospective study of 34 patients with CTCL treated with variable doses of pegylated liposomal doxorubicin, 20–40 mg/m<sup>2</sup> (26 received 20 mg/m<sup>2</sup>) every 2–4 weeks for eight cycles, revealed an OR of 88% (15 CR, 15 PR) [143].

#### **Drawbacks**

Hematological toxicity and infectious complications were reported. Palmoplantar erythrodysesthesia occurred rarely.

#### **Comments**

Pegylated liposomal doxorubicin is an effective and well-tolerated chemotherapeutic agent in CTCL.

### **Temozolamide**

#### **Efficacy**

There is one multicenter phase II trial of 26 patients with heavily pretreated MF (stages IB–IVB) at a dose of 200 mg/m<sup>2</sup> for 5 days every 28 days. The OR was 27% (8% CR, 19% PR) and the median disease-free survival was 4 months [144].

#### **Drawbacks**

Adverse events include hematologic, gastrointestinal, and constitutional toxicity.

#### **Comments**

Temazolamide is an oral derivative of dacarbazine, which enables easier administration and reduces hospital visits. Further studies are required to establish its efficacy.

### **What are the effects of multiagent chemotherapy regimens in mycosis fungoides and Sézary syndrome?**

#### **Combination chemotherapy**

#### **Efficacy**

A systematic review of all systemic therapy in CTCL (1988–1994) showed an OR of 81% in 331 patients treated with different combination chemotherapeutic regimens, with a CR of 38% and response duration ranging from 5 to 41 months, with no documented cures for patients with late stages of disease (IIB–IVB) [83].

Prospective nonrandomized studies of different multiagent chemotherapy regimens have revealed similar ORs. A combination of idarubicin, etoposide, cyclophosphamide, vincristine, prednisolone, and bleomycin (VICOP-B) was used to treat 25 CTCL patients (eight stage IIB, 13 stage IVA, four stage IVB) for 12 weeks. An OR of 80% with 36% CRs were documented, although 10 patients were treatment naive. The two patients with SS did not respond, and median response duration in patients with MF was 8.7 months. Stage IIB patients had a median duration of response of 22 months, but four previously untreated patients received additional TSEB therapy after completion of chemotherapy [145].

A combination of etoposide, vincristine, doxorubicin, cyclophosphamide, and prednisolone (EPOCH) was used to treat 15 patients with advanced, refractory CTCL (six SS; four stage IVB MF; one ATLL and four ALCL). After a median of five cycles, 27% had a CR and 53% achieved a PR, with an overall median survival of 13.5 months [146].

#### **Drawbacks**

Multiagent chemotherapy regimens are associated with very high rates of toxicity and morbidity, including nausea, anorexia,

infection, hepatotoxicity, and myelosuppression. Patients with CTCL are at high risk of septicemia, and therapy-related mortality is a significant risk.

### Comments

Patients with late stages of CTCL (IIB–IVB) will require treatment with a chemotherapy regimen, although the response duration is short. However, as overall survival rates are unchanged and toxicity may be considerable, these regimens are usually reserved for patients with extensive lymph node and visceral disease. Single-agent regimens appear to have similar efficacy, although studies involving a comparison between single-agent and multiagent regimens, with or without TSEB therapy, are required. Further well-designed studies of maintenance/adjuvant treatment with bio-immunotherapy, SDT or TSEB therapy for patients achieving a response with chemotherapy are required as patients frequently relapse with early-stage disease and there is currently no trial evidence that this approach improves outcome.

### Myeloablative chemotherapy with autologous or allogeneic hematopoietic stem cell transplantation

#### Efficacy

No RCTs were identified. Most studies were based on small numbers of patients. High-dose chemotherapy with TSEB therapy and total-body irradiation (TBI) in seven patients with MF (two patients had both TSEB therapy and TBI), followed by autologous bone-marrow transplantation in six patients (three stage IIB, one stage IVA, two stage IVB) produced five CRs, but three patients relapsed within 100 days [147]. The other two patients were disease free at almost 2 years.

High-dose chemotherapy combined with either TSEB therapy or TBI and followed by autologous peripheral blood stem-cell transplantation in nine patients with stage IIB/IVA MF revealed CRs in eight patients and durable clinical responses in four patients (median disease-free survival 11 months) [148].

A recent retrospective study of AHSCT included a heterogeneous group of 60 patients (36 MF and 15 SS) who received both myeloablative and reduced-intensity conditioning (RIC) regimens (45 matched related donor (MRD), 15 matched unrelated donor (MUD)) with an estimated 1-year survival of 66%, falling to 54% at 3 years [149]. RIC was associated with a decreased nonrelapse mortality without an increase in relapse/progression. MRD transplant patients had a better PFS and overall survival than those with an MUD. The risk of relapse was increased in patients who had undergone T-cell depletion. The transplant-related mortality at 1 year was 25%.

Another report described outcomes in 19 patients with advanced refractory CTCL who underwent an RIC regimen that included TSEB therapy, followed by allogeneic transplant using fludarabine/melphalan conditioning in 16 of the patients, with thymoglobulin for mismatched donors. Eighteen patients engrafted and one died of sepsis in the immediate posttransplant period. Fifteen reached full donor chimerism, 12 developed acute graft versus host disease (GvHD), and 12 developed chronic GvHD. The overall intent-to-treat response rate was 68% with a CR of 58%. Six patients died (two bacterial sepsis, one lung cancer, one chronic GvHD and fungal infection, and two PD). Skin relapse occurred in eight patients, five of whom had a CR with reduction of immunosuppression and donor lymphocyte infusions. Eleven patients remained in remission with a median follow up of 19 months [150].

### Drawbacks

Autologous-HSCT appears to be associated with only short-term remission and is therefore difficult to justify despite the limited data. Myeloablative AHSCT is associated with a high incidence of toxicity and systemic infections, and there is significant mortality. There is less toxicity with nonmyeloablative regimens, allowing treatment of older patients and those with comorbidities. The risk of life-threatening infection is lower with RIC allografts. Data available suggest that T-cell depletion with Alemtuzumab is associated with a higher rate of relapse and transplant-related mortality and should not be used in the conditioning regimen [149].

### Comments

AHSCT is successful in part because of the graft-versus-lymphoma effect of the donor graft, independent of the conditioning regimen, but this has to be balanced against the morbidity associated with chronic GvHD [150]. Maximal benefit from RIC-AHSCT is observed when performed before patients develop highly refractory disease and when there is low disease bulk at the time of transplantation [150]. Clinical trials to identify the optimal clinical conditioning regimen and timing of AHSCT in the course of the disease are required.

### Key points

- Although there are few well-designed RCTs in CTCL, there is evidence from uncontrolled studies that SDTs have a significant therapeutic effect and are the standard of care in patients with early-stage MF (IA–IIA).
- Patients with stage IA disease can have a normal life expectancy, and so aggressive therapies with a significant mortality and morbidity should be avoided, especially when the chance of a cure is very low.
- Patients with early-stage disease (IA/IB/IIA) should be offered SDTs such as topical mechlorethamine, phototherapy, PUVA, and superficial radiotherapy. Combinations of interferon alpha, bexarotene, or TSEB therapy should be considered for patients with persistent or recurrent stage IB/IIA disease. Some patients with stage IA disease may not require any specific therapy.
- Patients with late stages of disease (IIB/IV) should be offered TSEB therapy, single-agent palliative chemotherapy, and multiagent chemotherapy, according to performance status. Patients should be offered entry into a well-designed clinical trial if available.
- Patients with erythrodermic disease should be offered ECP, immunotherapy, alemtuzumab, and single-agent chemotherapy as palliative therapy, aiming to improve quality of life. TSEB therapy may be indicated for erythrodermic disease when there is a lack of significant peripheral blood tumor burden. Entry into a clinical trial should be offered, if available.
- In late-stage disease, adjuvant maintenance therapy should be offered where possible.
- The role of RIC-AHSCT in patients with advanced disease needs further study.

### Recommendations for the future

- New topical therapies should be assessed in the context of well-designed clinical trials.
- The role of new immunotherapies in early-stage (IB/IIA) disease should involve comparative RCTs with standard therapies.
- Future clinical trials in advanced disease (IIB–IV) are required to address the urgent need to improve overall survival, and future trials should also address a need to improve duration of response without increasing toxicity after PUVA and TSEB therapy.
- The role of RIC-AHSCT in patients with advanced disease needs further study.

## Abbreviations

AHSCT	allogeneic hematopoietic stem cell transplant
5-ALA	5-aminolevulinic acid
ALCL	primary cutaneous anaplastic large cell lymphoma
ATLL	HTLV-1 associated adult T-cell leukemia/lymphoma
BCNU	1,3-bis (2-chloroethyl)-1-nitrosourea
CR	complete response
CTCL	cutaneous T-cell lymphoma
DD	denileukin diftitox
ECP	extracorporeal photopheresis
EPOCH	etoposide, vincristine, doxorubicin, cyclophosphamide, and prednisolone
EORTC	European Organisation for the Research and Treatment of Cancer
FDA	United States Food and Drug Administration
FFR	freedom from recurrence
GvHD	graft versus host disease
HDACi	histone deacetylase inhibitor
HTLV-1	human T-lymphotropic virus type-1
IFN	interferon alpha
ISCL	International Society for Cutaneous Lymphomas
MF	mycosis fungoides
mSWAT	modified severity weighted assessment tool
NR	not recorded
OR	overall response
PD	progressive disease
PFS	progression free survival
PR	partial response
PTCL	peripheral T-cell lymphoma
PUVA	psoralen + ultraviolet A light
RCT	randomized clinical trial
RIC	reduced intensity conditioning
SD	stable disease
SDT	skin-directed therapy
SS	Sézary syndrome
TSEB	total skin electron beam
TBI	total body irradiation
UVB	ultraviolet B light
VICOP-B	Idarubicin, etoposide, cyclophosphamide, vincristine, prednisolone, and bleomycin

# Actinic keratosis and Bowen's disease

Sasha N. Jenkins, Maren Speck, and Suephy C. Chen

Department of Dermatology, Emory University School of Medicine, Atlanta, GA, USA

## Background

### Definition

Actinic keratoses (AKs), also known as solar or senile keratoses, and Bowen's disease (BD) are precursors of invasive squamous cell carcinoma (SCC). Whereas AK is precancerous, BD represents intraepidermal (in situ) SCC [1]. There is some evidence that AK lesions can be precursors to not only SCC but also to basal cell carcinomas [2]. AK presentation is characterized by multiple, erythematous, scaly papules that may be pink, red, or brown in color. AK lesions are typically less than 1 cm in diameter [3,4]. AK is termed "actinic cheilitis" or "solar cheilitis" if the lips are involved. BD usually presents as a solitary, well-demarcated, erythematous plaque of varying size, with irregular borders and a crusted, scaling, or fissured surface, usually persistent and enlarging (Figures 35.1 and 35.2) [5].

AK arises on areas of intense ultraviolet light exposure, with over 80% developing on the head and neck, forearms, and hands [6–8]. A male predominance is observed [4,9]. Other contributing factors include skin type, age, sun exposure, latitude, and ozone integrity [3,4]. The distribution of BD varies, demonstrating predominance on the lower legs in women and on the head and neck in men in the UK and Australia [10–12]. Australia and Denmark feature a marginal propensity of BD for women (56%) and occurrence on the head and neck (44–54%) [12,13]. Approximately one-third of patients with BD have other nonmelanoma skin cancers at diagnosis [13].

### Incidence/prevalence

The exact incidence and prevalence of AK and BD are unknown. Both increase in prevalence with advancing age [3,12,14,15]. AK may occur in children with albinism and xeroderma pigmentosum [16].

### Etiology

Chronic solar damage is the principal etiological factor in AK and BD [12,17–19]. People with light complexions, blue eyes, and childhood freckling are at highest risk, given their innate lack of protec-

tive pigment [6]. Individuals with compromised immunity (such as organ-transplant recipients), with diminished or absent melanin (such as albinos), and with decreased capacity to repair ultraviolet-induced damage (such as persons with xeroderma pigmentosum) all demonstrate an increased risk for AK. Risk factors for BD include arsenic exposure [20–23], immunosuppression [24], radiation, chronic injury, and human papillomavirus (HPV), particularly HPV-16 in anogenital lesions [25,26].

### Prognosis

Although the condition is precancerous [27,28], the probability of a given AK undergoing malignant transformation is unknown [15]. The reported risk of progression to SCC for individual lesions ranges from less than 1% to 16% per year [29]. The 10-year risk of malignant transformation of at least one AK on a given patient is 10% [30]. The relative risk of malignant transformation depends ultimately on factors related to the AK itself (for example, thickness), as well as patient characteristics (for example, drug therapy, degree of pigmentation, immune status) [4]. However, another aspect that may confound estimation of the prognosis of AK is the spontaneous regression rate. A study from Queensland [31] reported a spontaneous regression rate of 85% (95% confidence interval [CI], 75–96%) in people with prevalent AK (AK diagnosed on a person during the first examination) and 84% (95% CI, 72–96%) in persons with incident AK (AK appearing for the first time during the study). However, the distribution of lesions per person was highly skewed, with 12% of study participants having 65% of the total number of AKs. In the Veteran's Affairs topical tretinoin chemoprevention trial, the risk of progression from AK to primary SCC at 4 years was 2.6%, and the risk of progression from AK to primary BCC was 1.6% at 4 years [2].

BD is associated with an excellent prognosis, related to the disease's indolent nature and its favorable response to a range of therapies. Although there is no recent literature on the risk of BD progression to invasive SCC, older studies suggest the risk is 3–5% if lesions are left untreated [32,33]. Contrary to the findings of earlier reports [34–37], a meta-analysis of 12 studies in 1989 determined no significant association between BD and internal malignancy [38].

Figure 35.2 Bowen's disease.

### Aims of treatment

The aims of treatment are to achieve clinical and histological clearance, prevent progression to invasive SCC, prevent recurrence, achieve cosmetic improvement, and minimize adverse effects of treatment. One unique aspect of AK treatment is the decision to utilize spot versus field treatment, the former to focus on visible discrete lesions and the latter to treat an area that may have sub-clinical lesions. The studies reviewed below primarily focus on field treatment.

### Relevant outcomes

- Short-term clinical and histological clearance.
- Recurrence rates (these should be calculated at least 1 year following treatment, in order to assess the recurrence of AK and BD lesions adequately).
- Prevention of SCC.
- Adverse effects of treatment.

### Methods of search

Previously, a Medline search from 1966 to the end of December 2006 was performed to identify studies of 5-fluorouracil (5-FU) and cryotherapy in patients with AK. We also previously searched non-5-FU and non-nitrogen therapies by name and type, as well as the term "actinic keratosis treatment." In order to update this search,

we searched Medline and Embase from January 2007 to July 2012 using the same search methods. We scrutinized review articles for treatments not detected through database searches.

We limited the topic to non-anogenital BD and to publications written in English, since we did not have ready access to translation facilities. We reported numbers of patients as well as number of lesions treated wherever information was available. Studies that used patients as the unit of randomization (which makes the best clinical sense) were preferred over studies that used lesions as the unit of randomization without adjusting for a person effect.

Since few randomized controlled trials (RCTs) were found, uncontrolled trials were included in this chapter, with the exception of studies that had fewer than 10 patients, unless they were the only available studies. Currently, there is no available Cochrane review available; however, data are currently being collected for "Interventions of actinic keratoses." Evidence was graded using the quality-of-evidence scale employed the strength of recommendation taxonomy (SORT) criteria [39]. We have only presented data from the best-quality studies; for example, data from comparative studies are presented preferentially over data from case series when both exist for a given intervention.

## Questions

### What are the effects of non-drug therapy?

#### Cryotherapy

Cryotherapy involves delivering liquid nitrogen to affected areas with a spray device or cotton tip applicator. The mechanism of action of cryotherapy involves rapid cooling, resulting in intracellular ice crystal formation, followed by a slow thaw that results in cell damage [40]. Additional cycles lead to more damage. Since cryotherapy has been a longstanding mainstay of the treatment of AKs and BD, newer treatments have utilized cryotherapy as a comparison arm. We will discuss some of these comparisons in this cryotherapy section as well as in the other treatment sections below.

#### Actinic keratoses (strength of recommendation: A)

We evaluated one systematic review [41] and five RCTs (Table 35.1) [42–46]. All five RCTs were comparative studies. Two nonrandomized, uncontrolled studies investigating the effects of freeze time and temperature are also discussed [47].

**Benefits** The percentage of lesions that completely resolved with cryotherapy ranged from 66 to 88% in the five RCTs reviewed, although follow-up time varied between 3 months and 1 year. A single treatment with cryotherapy results in lesion response rates of 68–76% [42–44], while the response rate of lesions retreated at 3 or 6 months increased to 86–87% [42,45].

A nonrandomized, uncontrolled study found that the freeze duration may influence the success of cryotherapy treatment [47]. Complete responses in lesions with freeze times greater than 5 s were higher than responses for lesions with freeze times less than 5 s (69% compared with 39%). The complete response rate for lesions with freeze times greater than 20 s was 83% at 3-month follow-up [47]. Freeze temperature may affect outcome as well. A small, non-randomized study of 36 patients with 180 AKs found a 100% cure rate at 6 weeks when lesions were treated to a skin surface temperature of  $-5^{\circ}\text{C}$  using an integrated, infrared sensor [48].

The single study examined in the systematic review treated a total of 1018 lesions in 70 patients. Clinical follow-up after treatment

**Table 35.1** Summary of 5 RCTs using cryotherapy to treat AKs.

First author, ref	Intervention	Comparators	Study design	Study population	Sample size (n)	Outcome measures	Main results	Adverse effects	Study quality: Randomization <sup>a</sup> Blinding <sup>b</sup> Statistical analysis <sup>c</sup>

FTC: freeze–thaw cycle; MAL, methyl aminolevulinate; PDT, photodynamic therapy.

<sup>a</sup>Adequate if clear description of method of randomization and concealment of allocation of randomization.

<sup>b</sup>Adequate if assessors and participants were completely blinded to the study interventions.

<sup>c</sup>Adequate if an intention-to-treat analysis was carried out.

ranged from 1 to 8.5 years. Twelve recurrences were reported, giving a success rate of 99% during a follow-up period of 1–8.5 years [49].

**Harms** Adverse events associated with cryotherapy treatment include stinging, pain, or a burning sensation, erythema, edema of the skin, hyperpigmentation or hypopigmentation, blistering, skin infection, crusting, itch, and peeling [43,50]. However, the majority of events are of mild to moderate severity, are well tolerated, and are of short duration [44,50]. The percentages of patients who reported local adverse reactions after a single cryotherapy treatment ranged from 26 to 72% [42,44,45]. One study reported that 55% of patients treated with cryotherapy had clinically evident hypopigmentation at 12 months [46]. Unfortunately, the longer the duration of freezing, the more likely it is that an adverse event will occur. Very aggressive freezing may lead to a large blister, ulceration, longer healing times, more postoperative pain, and more pigimentary changes [51].

**Comment** Cryotherapy continues to be a popular and effective treatment for isolated AKs. Consideration should be given to the duration of treatment, since longer freeze times result in a greater response. Longer freeze times should particularly be used for larger lesions or those that are more hyperkeratotic. Cosmetic outcome remains a concern for both physicians and patients for cryotherapy: two RCTs investigating intraindividual methyl aminolevulinate (MAL) photodynamic therapy (PDT) and cryotherapy reported that only 21–22% of patients preferred cryotherapy as a treatment modality [42,45].

### **Bowen's disease (strength of recommendation: A)**

We found no systematic reviews and one RCT. The RCT was a comparison of cryotherapy ( $n = 20$  lesions) with PDT ( $n = 20$  lesions) [52]. One quasi-RCT compared the efficacy of MAL–PDT ( $n = 96$ ), placebo–PDT ( $n = 17$ ), cryotherapy ( $n = 82$ ), and fluorouracil ( $n = 30$ ) [53]. The patients were randomized to MAL–PDT, placebo, or standard therapy. The standard therapy was either cryotherapy ( $n = 82$ ) or 5-FU ( $n = 30$ ), chosen by the treating investigator. One unblinded controlled trial compared cryotherapy ( $n = 36$ ) with curettage ( $n = 44$ ) [54], and one retrospective study compared cryotherapy ( $n = 82$ ) with external beam radiotherapy ( $n = 59$ ) [55].

**Benefits** Across studies, PDT was superior to cryotherapy in the acute clearing of lesions after a single treatment. In addition, PDT had a lower recurrence rate with fewer adverse side effects [52,53]. Complete clinical clearance was comparable between cryotherapy (94% with one treatment and 100% with two) and curettage (100% after one treatment) 1 week after treatment. Overall, the average time to healing was 60 days. Healing was significantly prolonged for lower leg lesions treated by cryotherapy in comparison with curettage (90 vs 30 days;  $P < 0.001$ ). No difference in healing time was observed for other sites. Recurrence rates were lower (12% vs 50%;  $P < 0.04$ ) and the time to recurrence was longer ( $P < 0.0087$ ) for curettage compared to cryotherapy [54].

**Harms** Complications of cryotherapy include pain, poor healing, and infection, requiring antibiotics [56]. Pain of mild to moderate severity was reported in 19 of 20 lesions during cryotherapy, which

was significantly higher than pain reported during PDT ( $P < 0.01$ ) [52]. Ulceration occurred in five of the 20 lesions, and two of the five patients concerned were later prescribed antibiotics for cellulitis developing around the lesions. Visible scarring in four of the 20 lesions was observed at 12 months posttreatment [52]. Patients were 10.4 times more likely to report pain with cryotherapy ( $P < 0.001$ ) and were 5.5 times more likely to report pain on the lower leg in comparison with other body sites, irrespective of the treatment method used ( $P < 0.016$ ) [54]. Poor healing occurred in 2% of patients who received cryotherapy in this retrospective comparison study with radiotherapy [55]. Biopsy of these poorly healing lesions revealed residual tumor. The authors speculated that failure to heal may suggest residual BD and may be an indication for surgical excision.

**Comment** These studies report high short-term clearance rates with liquid-nitrogen cryotherapy, although poor healing, as well as discomfort related to the procedure, may limit its utility in BD of such sites as the lower legs. In relation to the study comparing cryotherapy and curettage, methodological limitations include deviation from an intention-to-treat (ITT) analysis and use of nonrandom allocation. The former omission would tend to overestimate the efficacy of the intervention, whereas the latter would tend to weaken the validity of the results, as there is no assurance that known and unknown confounders are homogeneously distributed between the comparison groups. The treatment protocol in these studies varied on how aggressive the treatment was, thus making it difficult to determine the adequate amount of cryotherapy to attain the lowest recurrence rate. However, a more aggressive approach consisting of 20 s at least twice or 30 s at least once might yield better results.

### Laser treatment

Studies investigating ablative skin resurfacing with erbium–yttrium aluminum garnet (Er:YAG) laser for AK and BD highlight its capacity to selectively vaporize the epidermis and upper papillary layer with minimal scar formation. We found no systemic reviews for Er:YAG laser for either AK or BD, and no RCTs for BD.

Fractional photothermolysis is a nonablative or minimally ablative therapy which treats only fractions of the skin by inducing small areas of damage, referred to as “microscopic thermal zones.” The surrounding tissue is undamaged and allows for faster epidermal repair. Noncontact fractional photothermolysis, performed with the handpiece held several millimeters above the skin surface, is hypothesized to result in targeted damage in the epidermis and dermal–epidermal junction, resulting in a “quasi-ablative” effect. There are no RCTs for fractional photothermolysis of AK or BD.

### Actinic keratoses (strength of recommendation: B)

**Erbium–yttrium aluminum garnet and carbon dioxide lasers** The single RCT we reviewed was a comparison study between laser resurfacing with an Er:YAG laser and topical 5-FU in the treatment of AK [57]. In addition, we considered an uncontrolled prospective study as well as two retrospective reviews (Table 35.2) [58–60].

**Fractional photothermolysis** We reviewed two uncontrolled prospective trials investigating the use of fractional photothermolysis in AK. One trial examined the use of a 1550 nm fractionated erbium-doped fiber laser in the treatment of 348 AKs in 14 patients, using both clinical and histological endpoints at 3 and 6 months [61]. An additional uncontrolled trial investigated the use of

**Table 35.2** Summary of RCT and studies investigating ablative laser therapy to treat AKs.

First author, ref.	Intervention	Comparators	Study design	Study population	Sample size (n)	Outcome measures	Main results	Adverse effects	Study quality: Randomization <sup>a</sup> Blinding <sup>b</sup> Statistical analysis <sup>c</sup>

<sup>a</sup>Adequate if clear description of method of randomization and concealment of allocation of randomization.

<sup>b</sup>Adequate if assessors and participants were completely blinded to the study interventions.

<sup>c</sup>Adequate if an intention-to-treat analysis was carried out.

noncontact fractional 1540 nm erbium/glass laser (Er:glass) in 17 patients with 3-month follow-up [62].

**Benefits of erbium–yttrium aluminum garnet** Combined data from the RCT and two retrospective studies suggest ablative laser therapy is very successful at reduction in AK burden, with a 91–94% decrease in numbers of AKs 1 year after treatment [57,59].

**Benefits of fractional photothermolysis** An uncontrolled prospective trial investigating the use of a 1550 nm fractionated erbium-doped fiber laser demonstrated that clinical AK count was reduced on average by 73% at 1 month, but this decreased to 66% at 3 months, and to 56% by 6 months [61].

In the uncontrolled prospective trial investigating the use of a 1540 nm Er:glass laser, reduction in AKs was scored on a scale of 0–4 (0: no improvement; 1: 1–25% reduction; 2: 26–50%; 3: 51–75%; 4: 76–100%). Following their first treatment, patients had a mean improvement of 2.4 on a scale of 0–4, and this increased to 2.9 following their second treatment, and up to 3.3 at 3 months after completing therapy [62].

**Harms** Ablative laser therapy may be associated with erythema, edema, infections, crust formation, pain, irritation, itching, hypopigmentation, acne, milia, and scarring [57,59,60]. Re-epithelialization usually occurs within 5–15 days after treatment, but may take longer for larger lesions. Most adverse effects are transient, but some such as dyschromia, atrophy/easy bruising, itching, and persistent crusting may last for over 6 months [60]. Both retrospective reviews reported occurrence of nonmelanoma skin cancers within treated fields in 8–12% of patients during follow-up of at least 1 year [59].

Fractional photothermolysis is associated with fewer adverse effects than ablative laser therapy, typically causing transient mild to moderate erythema, mild edema, superficial peeling, or superficial erosions without reports of scarring or postinflammatory hyperpigmentation in either study reviewed [61,62]. However, the prospective study of 14 patients treated with erbium-doped fiber laser found that, despite clinical improvement, 12/14 biopsies taken at 3 months posttreatment were positive for histologic features of AK and/or SCC [61].

**Comments** Ablative laser therapy appears to be highly effective in the immediate treatment of AK lesions. However, there are few studies with long-term follow-up, and those that have been done report variable recurrence rates. Side effects associated with this treatment may also produce long-term, undesirable cosmetic outcomes. In addition, laser therapy is a more expensive treatment in comparison with other treatment modalities such as 5-FU and cryosurgery. Further studies should be performed before Er:YAG or CO<sub>2</sub> laser therapy can become a routine treatment for AK. There are inadequate data to support fractional photothermolysis as monotherapy in the treatment of AK.

#### **Bowen's disease (strength of recommendation: B)**

The largest uncontrolled trial, a retrospective review, reported 44 patients with BD treated with CO<sub>2</sub> laser with 4 mm margins with a mean follow-up of 18 months [63]. A second uncontrolled trial reported the use of CO<sub>2</sub> laser therapy for BD on the legs [64]. This study treated 16 patients with 25 lesions with a 6-month follow-up. An update on patient health 12 months after discharge from this study was also published [65].

**Benefits** The larger study of 44 patients with BD treated with CO<sub>2</sub> laser showed a clearance rate of 98% overall, with a recurrence rate of 7% over a follow-up period between 8 and 52 months [63]. Only one treatment session was required for 86% of patients, while 11% of patients required more than one treatment session, with only one person not responding [63]. The study that treated BD on the legs found that eight of the 25 lesions took longer than 4 weeks to heal, but all lesions had healed completely at 8 weeks after treatment. Examination at 6 months found no recurrence of BD lesions, but at the 12-month follow-up there was a 12% recurrence of invasive SCC [64,65].

**Harms** Exudation, crusting, and erythema may follow laser treatment. Re-epithelialization occurs 7–10 days after treatment, but erythema may persist for 3 weeks or more. One Er:YAG laser study found no posttherapeutic dyspigmentation [66]. Secondary adverse effects occurred in 32% of patients, including minimal erythema and hypo- and hyperpigmentation, in one study, with only one patient acquiring a keloid [63]. Two of the 16 patients receiving CO<sub>2</sub> laser treatment on the legs developed infections requiring dressings and antibiotics [64]. No other adverse events were reported in this study; however, the study was published as an abstract in conference proceedings, and a detailed summary of all of the results was not provided.

**Comment** CO<sub>2</sub> lasers may be an alternate method for treating BD that allows for limited tissue injury resulting in better healing. However, if the tumor is deeper than expected, clearance rates may be inferior. Given that the progression to invasive malignancy was higher than expected (12%) in patients receiving laser treatment for BD on the legs [62], careful consideration should be given to the use of laser therapy until further studies are performed. Of note, there have been two small uncontrolled trials reporting the use of CO<sub>2</sub> laser therapy for BD on the digits, with either five or six patients, with a reported clearance rate of 100% within 10–24 days following the procedure [67,68]. However, recurrence rates differed between 0% at 84 months [68] and 20% at 5 months [67], likely due to difference in energy settings and margins. In these studies, CO<sub>2</sub> laser had no impairment of digital function. The suitability of CO<sub>2</sub> laser therapy for digital BD relates principally to two properties. First, CO<sub>2</sub> laser has the ability to vaporize the epidermis and the upper papillary dermis, leading to healing with minimal scar formation. This feature is desirable in mobile areas such as the fingers, where a contracting scar following excision may lead to functional impairment. Second, the concern that CO<sub>2</sub> lasers may not penetrate to a depth sufficient to eradicate perifollicular BD is obviated by the paucity of hair on the fingers. The risk of recurrence secondary to perifollicular involvement is therefore less of a concern in digital lesions than in lesions at other body sites. CO<sub>2</sub> lasers may thus be helpful for digital lesions, while other treatment options should be explored for lesions at other body sites until further studies are performed.

#### **Radiotherapy**

We found no systematic reviews or RCTs for either AK or BD.

#### **Actinic keratoses (strength of recommendation: C)**

We found only one case report using radiotherapy for AK [69].

**Benefit** One person with a large AK recalcitrant to 5-FU responded to fractionated radiotherapy [70].

**Comment** Given the absence of high-quality evidence for radiotherapy and the availability of other therapeutic modalities, radiotherapy should not be used for the treatment of AK.

#### **Bowen's disease (strength of recommendation: B)**

We found one retrospective study comparing the effect of radiotherapy with cryotherapy on lower leg lesions [55], as reported above. We also found two retrospective reviews, one of which contained 44 patients with BD treated with radiation therapy with a median follow-up of 2.6 years [71], and a smaller one with 11 patients with 16 BD lesions treated with radiotherapy [72].

**Benefits** Radiotherapy was more effective than cryotherapy in terms of recurrence (0% vs 6% at 2 years posttreatment) [55]. Skin cosmesis following radiotherapy is reported as "good" to "excellent" in the majority of patients in uncontrolled trials, with only 5–15% of irradiated skin considered "fair" to "unsatisfactory" [70,73]. In the study of 44 patients, orthovoltage X-rays were used, but there was no standard fractionation regimen. Complete remission occurred in 95% of patients, with a recurrence rate of 0.07% [71]. In this study, there was not a statistically significant association between the biologically effective dose and the recurrence rate [71]. All BD lesions followed in the retrospective study had 100% clearance at the time of last follow-up (the follow-up periods ranged from 17 to 1723 days) [72].

**Harms** The 100% clinical clearance and lack of recurrence using radiotherapy of leg lesions was offset by poor healing in 20% of lesions [55]. Poor healing in this study was defined as a residual ulcer requiring salvage surgery that ceased to show signs of continuing reduction in diameter, or was considered by the dermatologist to be progressing poorly over at least 3 months. In the larger retrospective study, the three BDs that were treated with higher radiation doses, all on extremities, resulted in Grade 4 toxicity, resulting in ulcers, one of which required amputation secondary to radiation necrosis [71]. The small retrospective study also reported poor healing, with 25% of lesions failing to heal due to ulcers, all of which were located on the lower leg [72]. Other reported adverse effects from uncontrolled studies included minor pain and burning during the procedure [74,75], short-term hypopigmentation [74], radiation dermatitis, and radionecrosis [75]. Poor healing, including radionecrosis, appears to be associated with older age, an irradiation field diameter >4 cm, and a total dose >3000 cGy [55,75].

**Comment** As noted by the authors of the retrospective comparative study of radiotherapy and cryotherapy, the conclusions must be considered in the light of the noncomparability of the groups. This study was retrospective, and shows a selection bias inasmuch as the severity and extent of a lesion often determines its initial therapy. A higher proportion of broad and thick lesions were thus treated in the radiotherapy group. Considering the radiotherapy group alone, however, may be informative in that poor healing was significantly related to age >90 years, a field irradiation diameter >4 cm, and a radiotherapy dose >3000 cGy. In view of the risk for poor healing, the authors suggested that patients meeting these criteria require cautious consideration in determining their candidacy for radiotherapy. However, in the larger retrospective study of 44 BDs treated with radiotherapy, there was no association between the biologically effective dose and recurrence, thus possibly allowing for effectiveness of lower doses with the prevention of treatment toxicity [71]. Caution should be used when selecting patients for

radiotherapy who have lesions in potentially poorly healing areas such as the lower legs, and moderate radiation treatment doses can result in a high rate of local control, reducing the potential for ulcer complications. Radiation therapy may be an option for larger lesions not amenable to other modalities in older patients.

#### **Chemical peels**

Chemical peels have only been investigated for AK.

#### **Actinic keratosis (strength of recommendation: A)**

We found no systematic reviews and one RCT. The RCT was a within-patient comparison of 5-FU combined with a glycolic acid (GA) peel versus the GA peel alone ( $n = 18$ ) [76]. We found two comparative studies [77,78] (with one follow-up study [79]) using trichloroacetic acid (TCA). Pretreatments included topical tretinoin (0.05%, increasing to 0.1%) in the first study [77] and Jessner's solution in the second study [78,79]. The concentrations of TCA varied from 35 to 40%.

The first study [77] was reportedly randomized. However, all of the patients pretreated with tretinoin had previously received topical therapies in addition to cryotherapy, whereas all of the patients without tretinoin pretreatment had previously received only cryotherapy. The study reported a 6-month follow-up. In the second study, a split-face design was used. One side of the face received a TCA chemical peel after pretreatment with Jessner's solution, and the other side received 5% topical 5-FU twice daily for 3 weeks. Despite a small sample size, follow-up was reported at 12 months [78] and 32 months [79].

**Benefits** Six months after eight weekly pulse peels, the combination of 5-FU and GA had cleared significantly more lesions than GA alone (92% vs 20%;  $P < 0.05$ ) [76]. No significant differences were observed for pretreatment with topical tretinoin before 40% TCA; AK was reduced by 20–75% in both groups. The authors used a reduction in the appearance of lesions, which was not necessarily a reduction in the number of lesions. Scores for photodamage decreased and telangiectasias improved with tretinoin pretreatment. Jessner's solution followed by TCA did not differ significantly from topical 5-FU: both yielded a 75% reduction in the number of lesions that persisted for 12 months. Analysis of eight patients at the 32-month follow-up showed that three (37%) had more lesions than at baseline, but that three patients maintained a 50% reduction from baseline.

The patients were extremely pleased with the cosmetic results of the TCA facial peels, and scored improvement significantly higher than the clinicians did. Patients preferred the facial peel to 5-FU because of the convenient single application and the shorter duration of adverse effects.

**Harms** Few side effects were associated with the combination GA peel and 5-FU or the GA peel alone. Slight facial erythema and mild xerosis were experienced, but resolved with an emollient cream [76]. The medium-depth facial peel procedures were associated with erythema lasting generally 10 days to 2 weeks. Mild desquamation was noted.

**Comments** The combination of 5-FU with a GA peel is more effective than a GA peel alone, which is likely too superficial to treat AKs. An RCT comparing 5-FU alone with 5-FU plus a GA peel would further elucidate what role, if any, GA has in the treatment of AK. Facial peel with TCA appears to be a viable option if the

patient is not a good candidate for cryotherapy (i.e., with widespread facial AK), or is intolerant to other topicals applied over the long term, such as 5-FU.

### Dermabrasion

Dermabrasion was investigated only for AK.

#### *Actinic keratosis (strength of recommendation: C)*

We found one unblinded comparative study [80] comparing recurrence rates for dermabrasion, 50% phenol chemical peels, and 1% topical 5-FU. Methodological problems included a small sample size, varying follow-up periods, lack of data on initial elimination rate, and lack of explicit evaluation criteria for remission or recurrence.

**Benefits** Dermabrasion yielded a longer time to recurrence than facial peel, but shorter times than 5-FU. However, no statistical data were presented [80].

**Harms** No information on adverse events was reported in the unblinded study. One case series of dermabrasion of the scalp [81] reported a conspicuous line marking the periphery of abrasion at postoperative weeks 6–8.

**Comments** This small study concluded that topical 5-FU was more effective and easier to use than dermabrasion. Although dermabrasion may produce longer term clearance than chemical peels, the case series [81] indicated a risk of scarring. Although larger studies are necessary for definitive conclusions to be reached, it would appear that the indication for dermabrasion as a primary therapeutic modality for AK is minimal.

### Surgery and electrodesiccation and curettage

Surgery is commonly used for BD, but not for AK.

#### *Bowen's disease (strength of recommendation: B)*

We found no systematic reviews or RCTs. We found one retrospective uncontrolled trial investigating surgical excision ( $n = 109$ ), as well as curettage and fulguration ( $n = 46$ ) and electrodesiccation ( $n = 16$ ) [82]. We found smaller retrospective uncontrolled trials for electrodesiccation and curettage (ED&C) ( $n = 20$  [83],  $n = 83$  [70],  $n = 52$  [84]). We found one prospective trial that compared cryotherapy ( $n = 36$ ) with ED&C ( $n = 44$ ) [54].

**Benefits** The 5-year recurrence rate, calculated by Kaplan–Meier curves, of surgical excision was 6% [82]. In this same study, the recurrence rate of curettage and fulguration was 7% based upon a mean follow-up duration of 28.7 months. There were no recurrences in electrodesiccation alone [82]. ED&C [70,83,84] resulted in complete clinical clearance rates ranging from 80 to 98%, with recurrences ranging from 2% up to 20% during a follow-up period of up to 18 years. Again, the time to recurrence was not reported. In the prospective study comparing cryotherapy with ED&C, there was a 100% clearance rate with a 9% recurrence rate over a 2-year follow-up period for ED&C, compared with a 36% recurrence rate for cryotherapy [54].

**Harms** No harms were reported with ED&C or with surgical excision, other than the understood risks of bleeding, infection,

scarring, and local anesthesia associated with minor surgery. ED&C compared with cryotherapy had superior healing, including decreased time to heal, with less pain and morbidity with ED&C [54].

**Comment** Surgical excision is commonly reported as the treatment of choice for BD, although no RCTs and only a few retrospective and one prospective series were found to support its use. The unmatched efficacy ascribed to surgical excision probably relates to the notion that excision of an in-situ neoplasm is, by definition, curative. The slow progression of BD to SCC suggests that additional outcomes such as healing, scarring, and patient preferences should be considered in determining the choice of treatment. The large series investigating ED&C suggested high efficacy, with tolerable recurrence rates during a sufficiently long follow-up period. ED&C may thus be a highly useful procedure for patients with small solitary lesions.

### What are the effects of topical therapy?

#### Topical retinoids

Topical retinoids were reported only for AK.

#### *Actinic keratoses (strength of recommendation: B)*

We found four double-blind RCTs investigating topical retinoids for AK [85–88]. The first study compared tretinoin cream ( $n = 25$ ) with Ro 14-9706 (arotinoid methyl sulfone cream;  $n = 25$ ) using a split-face design [85]. The second study was a parallel-group multicenter trial comparing 0.1% isotretinoin ( $n = 41$ ) with placebo ( $n = 47$ ) [86]. The third study was a four-arm comparison trial investigating the use of *all-trans*-retinoic acid cream, calcipotriol cream, a combination of the two creams, and a vehicle cream in renal transplant recipients [87]. Thirteen patients with multiple AKs applied each of the four treatments to different lesions, the order of which was randomly assigned. The fourth study compared the efficacy of 0.1% adapalene gel ( $n = 30$ ), 0.3% adapalene gel ( $n = 30$ ), and a vehicle gel ( $n = 30$ ) [88].

We also reviewed a large RCT comparing tretinoin versus vehicle cream in the prevention of keratinocyte cancers; response rates of AKs were reported as a secondary outcome ( $n = 1131$ ) [89].

**Benefit** Reductions in the number of AK lesions by 30% and 38% were reported for tretinoin and Ro 14-9706, respectively. Complete clearance of all lesions occurred in 8% of patients using tretinoin [85]. In comparison with placebo, 0.1% topical isotretinoin significantly reduced the number of facial lesions (65% vs 45%;  $P < 0.005$ ) [86]. No differences in the number of AK lesions were found between each of the four treatments used in the third study after 6 weeks of treatment [87]. It was concluded by the authors that neither *all-trans*-retinoic acid nor calcipotriol, nor a combination of these two creams, should be used to treat AKs in renal transplant recipients. After 9 months of treatment, patients treated with 0.3% adapalene gel had significantly fewer lesions in comparison with the baseline than those treated with vehicle cream ( $P < 0.05$ ) [88]. The complete lesion clearance rate for patients in both adapalene treatment groups was only 3%, while an increase in the numbers of lesions was observed in the vehicle group.

The RCT which examined the use of tretinoin 0.1% cream in the chemoprevention of keratinocyte cancers did not demonstrate any significant difference in AK counts between intervention and placebo [89].

**Harms** Severe local skin irritation was associated with topical tretinoin, whereas the irritation was mild to moderate with isotretinoin. No significant changes in laboratory parameters were observed. Higher levels of erythema, peeling, dryness, burning, and pruritus were associated with 0.3% and 0.1% adapalene treatment in comparison with the vehicle treatment [88].

The RCT comparing topical tretinoin with vehicle in the chemoprevention of BCC and SCC failed to show any significant difference in rates of nonmelanoma skin cancer: 53% of patients treated with tretinoin versus 54% of those treated with vehicle developed a BCC within 5 years, and 28% of the treated group developed an SCC compared with 31% of those treated with placebo. In addition, all-cause mortality was higher in the tretinoin group, although there is no clear causality between treatment and increased rates of patient death [89].

**Comments** Although some reduction in AK counts and size has been noted, few patients (8% [77] and 3% [88]) had complete clearance of lesions. In addition, tretinoin failed to prevent the development of nonmelanoma skin cancers [89]. The relatively high rate of reduction noted with placebo use indicates either that the study was flawed or that topical retinoids may not enhance the clearance of AK lesions sufficiently to be used as a standard treatment for AK.

### 5-Fluorouracil

Topical chemotherapy with 5-FU interferes with DNA and RNA synthesis. It is primarily used as a field treatment, for diffuse, ill-defined AK in which treatment of individual lesions is impractical or impossible. It is also used in BD.

#### *Actinic keratoses (strength of recommendation: A)*

We considered three systematic reviews [90–92]. There was significant overlap among the studies included in the systematic reviews.

**Benefits** The first systematic review combined 13 RCTs [57,93–104] to include in a meta-analysis [90]. The review included and compared studies which used either 0.5% or 5% 5-FU to treat lesions on the face, scalp, and extremities. Several measures of efficacy were assessed, including the average reduction in the mean number of lesions, the percentage of lesions cleared, as well as the number of patients with complete clearance at follow-up. Follow-up times for the included studies ranged from 4 weeks to 12 months. The combined data showed that treatment with 5% 5-FU resulted in an average reduction of 80% (59–100%) [57,93,94,97,100] in the mean number of lesions with 98% of lesions clear at 4 weeks [102] and 94% at 24 weeks [103] following treatment. Treatment with 0.5% 5-FU resulted in an average reduction of 86% (78–92%) in the mean number of lesions [95,104]. Across studies, an average of 49% (0–96%) of patients treated with 5% 5-FU and 35% (15–58%) of those treated with 0.5% 5-FU achieved total clearance [90].

The second systematic review combined six studies [78,95,104–107] to include in a meta-analysis [91]. The studies included used 0.5%, 1%, or 5% 5-FU as treatment, treated only the face and/or scalp, and measured the proportion of patients with no visible AKs at follow-up. The proportion of patients with complete clearance ranged from 0 to 100% (with treatment periods of 2–8 weeks and follow-up periods of 1–11 months). The pooled average for patient response was  $52.2 \pm 18\%$ .

The final systematic review combined nine studies [95,96,98,100,101,104,106–108] of 5-FU at either 5% or 0.5% concentration used on the face and/or scalp [92]. Efficacy was meas-

ured as complete clearance of all AKs at 4 weeks posttreatment for 0.5% 5-FU and 4–6 weeks posttreatment for the 5% 5-FU studies. Complete clearance rates with 0.5% 5-FU ranged from 15 to 58%, and those with 5% 5-FU from 43 to 100%. The single split-face study comparing 5% with 0.5% 5-FU had equivalent rates of complete clearance (43%) [100].

**Harms** 5-FU can be associated with pain, inflammation, and erosions. In the split-face study, twice-daily 5% 5-FU was found to cause more irritation, erosions, dryness, burning, pruritus, pain, and edema than once-daily 0.5% 5-FU [100].

**Comments** Although 5-FU has a high efficacy rate, one should note that it is associated with a high degree of morbidity, including pain, inflammation, and erosions, which may be intolerable to patients.

#### *Bowen's disease (strength of recommendation: A)*

We found no systematic reviews and two RCTs. One RCT was a comparison trial between 5% 5-FU and PDT [109], while the other was an RCT comparing MAL-PDT, cryotherapy, and 5-FU [53]. We found five uncontrolled trials addressing the therapeutic efficacy of 5-FU [82,110–113].

**Benefits** One year after treatment with either PDT or 5-FU, the complete clinical clearance rate of lesions in the 5-FU group was significantly less than in the PDT group (48% vs 88%;  $P = 0.006$ ) [109]. In the second RCT evaluated, the sustained complete response rate at 1 year of 5-FU was comparable to that of MAL-PDT ( $P = 0.19$ ); both were superior to cryotherapy ( $P = 0.047$ ). The clearance rate for 5-FU was 83% compared with 93% for PDT, but both superior to cryotherapy [53]. In the uncontrolled trials, clinical clearance rates were generally high, ranging from 85% [112] to 100% [83].

**Harms** Expected side effects include pain, pruritus, burning at the site of application, erythema, inflammation, widespread dermatitis reactions, and erosions [56,109,114]. In the nonrandomized studies, some authors suggest application of the medication four times daily to reduce the duration of treatment [110], while others advocate pulse therapy once or twice weekly to decrease the intensity of discomfort [115]. Although compliance with the latter regimen is higher, cure rates may be lower [116]. Lower-leg ulceration has been reported with 5% 5-FU cream [109,110], and an allergic reaction to 5-FU has been reported in conjunction with iontophoretic therapy [113].

**Comment** 5-FU appears to be of likely benefit in treating BD, although PDT maybe superior. As with AK, if patients are unable to tolerate the side effects of 5-FU, then we would expect the cure rate to drop off dramatically. For example, in the RCT, treatment was discontinued in five of the 33 lesions treated with 5-FU due to widespread dermatitic reactions (compared with none of 33 in the PDT group), which likely explains the low clearance rates for this treatment group (48%) [109].

The base in which 5-FU is delivered significantly affects its activity: 20% 5-FU in an ointment base, 5% 5-FU in a cream base, and 1% 5-FU in propylene glycol provide approximately equivalent cytotoxic activity [106,117–119]. Several studies investigated ways of enhancing 5-FU activity. Iontophoresis does not appear to improve 5-FU activity in comparison with 5-FU alone, but possibly could have the benefit of delivering 5-FU into adnexal structures

[70,83,112,113]. Application under occlusion, pretreatment with keratolytic agents, or deliberate exposure to sunlight (photosensitivity effect of 5-FU) are anecdotally reported as enhancement techniques [83]. The disparity in recurrence rates may relate to different therapeutic regimens: the recurrence rates were lower for studies that used 5-FU for longer than 4 weeks [83,112].

### Imiquimod

Imiquimod is an immunomodulator used as topical field treatment for AK. It is an agonist of toll-like receptor 7, which results in activation of both innate and adaptive immune responses [120,121]. It is available in two different concentrations (5% and 3.75%), and several regimens are used for treatment of AK.

#### *Actinic keratoses (strength of recommendation: A)*

We found three systematic reviews [91,122,123] with meta-analyses of RCTs [122,123] or RCTs and other relevant studies [91], which assessed the efficacy of 5% imiquimod in treating AK (Table 35.3). The first review [122] included five studies in its meta-analysis

[124–128], the second review [123] included four studies [124,125,127,128], and the third review [91] also included four studies [125,127–129]. We also reviewed six RCTs investigating the efficacy of alternate dosing schedules and concentrations of imiquimod [98,130–134].

**Benefit** A total of 1293 patients clinically or histologically diagnosed with AK were evaluated in the RCTs included in the first systematic review [122]. All of these studies sufficiently measured both the benefits and harms of imiquimod, but only one study [135] had a long enough follow-up period ( $\geq 1$  year) to effectively assess recurrence rates. Complete clinical clearance of all AK lesions occurred in 50% of patients treated with imiquimod, in comparison with only 5% in those treated with a vehicle cream [122]. The mean clinical response was not calculated in the second systematic review, which included 1266 patients [123], but complete clearance of lesions was more common in imiquimod-treated patients than in control-treated patients ( $P < 0.0001$ ). The third systematic review, which included a total of 393 patients, reported slightly higher

**Table 35.3** Summary of RCTs using imiquimod to treated AKs.

First author, ref	Intervention	Comparators	Study design	Study population	Sample size (n)	Outcome measures	Main results	Adverse effects	Study quality: Randomization <sup>a</sup> Blinding <sup>b</sup> Statistical analysis <sup>c</sup>
Swanson (2010) [130]	2.5 and 3.75% imiquimod applied daily $\times 2$ , 2-week cycles	Placebo	RCT	AKs on face and scalp	479	Percentage of patients with complete clearance at 8 weeks	2.5% placebo 23.5% imiquimod 2.5% 26% imiquimod 3.75%	24–25% erythema 4–6% edema 1–6 % weeping/exudate 4–8% flaking/scaling/dryness 9–14% scabbing/crusting 9–11% erosions/ulceration	Adequate Adequate Adequate

Krawtchenko (2007) [98]	5% imiquimod TID $\times 4$ weeks for 1 or 2 cycles	Cryotherapy and 5-FU	RCT	AKs on head, neck or chest	75	Percentage of patients with complete clearance at 8 weeks	85% imiquimod 68% cryo 96% 5-FU	Not specified	Adequate Not adequate Not described

TID, three times a day; TIW, three times a week.

<sup>a</sup>Adequate if clear description of method of randomization and concealment of allocation of randomization.

<sup>b</sup>Adequate if assessors and participants were completely blinded to the study interventions.

<sup>c</sup>Adequate if an intention-to-treat analysis was carried out.

efficacy rates with imiquimod. The proportion of patients with complete clinical clearance for this review was  $71 \pm 12\%$  (mean plus/minus 95% CI) [122].

The RCTs reviewed (see Table 35.1) explored several different treatment regimens and demonstrated complete clearance rates of AKs on the head between 24 and 26% in patients treated with two cycles of 2.5% or 3.75% imiquimod daily for 2 weeks [130]. Efficacy increased to 34% complete clearance with two cycles of daily 3.75% imiquimod for 3 weeks [131]. AKs on the forearms and hands appear to be less responsive to treatment according to one study, which documented complete clearance rates of only 3–7% with 5% imiquimod applied for two, three, five, or seven times per week for 8 weeks, and did not to demonstrate a dose-dependent response [132]. The 5% imiquimod cream applied three times a week for a single 4-week cycle led to a 22–27% rate of complete clearance, while two 4-week cycles increased the percentage of patients cleared to 54–85% [98,133,134]. Histologic clearance was confirmed in 73% of lesions that demonstrated clinical resolution [98]. Of the patients that were clinically clear at 8 weeks following treatment, 73% remained clear at a 12-month check [98].

**Harms** Many local adverse events are associated with imiquimod treatment, including erythema, scabbing or crusting, flaking, erosion, edema, and weeping [122]. Use of imiquimod is also associated with influenza-like symptoms in up to 8% of patients [131,132]. Several studies noted that better clearance was observed in patients with the most severe adverse events [124,135]. Some authors also reported that the number of AK lesions increased in the initial stages of treatment [124–126]. It was proposed that this was more likely to be an appearance of subclinical lesions rather than formation of new lesions, and considered to be a benefit of imiquimod treatment.

**Comment** There is good evidence that imiquimod is an effective treatment for AKs on the face and scalp. Given the local adverse reaction that so commonly appears with imiquimod, we question whether the studies that were designed to be double blinded could have truly achieved blinding of the subjects who applied the cream. The FDA-approved guideline for use of imiquimod for treatment of AKs is twice weekly for 16 weeks. There appear to be multiple comparable dosing regimens that can be tailored to the needs and preferences of individual patients. Imiquimod treatment of AKs on the extremities appears to be less effective, and alternative treatments may be more appropriate in this area.

#### **Bowen's disease (strength of recommendation: A)**

We found a single, small RCT and two uncontrolled trials. The double-blinded RCT randomly assigned 31 patients to receive either a placebo cream ( $n = 16$ ) or imiquimod ( $n = 15$ ) daily for 16 weeks [136]. The largest retrospective review included 49 patients with BD treated with once-daily application of imiquimod for 6 weeks [137], while the other smaller uncontrolled trial treated 16 lesions of the lower limbs with once-daily application of imiquimod cream for 16 weeks [138].

**Benefits** The RCT reported that 73% of imiquimod-treated patients (once-daily application for 16 weeks) achieved complete resolution of BD lesions, which was significantly greater than in the placebo group, in which no resolution was achieved ( $P < 0.001$ ), with a follow-up period of 28 weeks [136]. In the larger retrospective review with 49 patients, there was an 86% clinical clearance rate

over a mean follow-up of 19 months in patients using imiquimod (once-daily application over mean of 9 weeks). In 10% of the patients who failed therapy, they had no discernible inflammatory reaction [137]. The second uncontrolled study reported a 93% treatment response (15 of 16 patients), evidenced by no residual tumor on histology, over a mean follow-up time of 6 months [138]. Although six patients withdrew prematurely because of local skin reactions and were not included in the final analysis, an ITT analysis showed that 88% (14 of 16 patients) had no residual tumor [138].

**Harms** In the RCT, imiquimod treatment was generally well tolerated, and no serious adverse events were reported [136]. Two imiquimod-treated patients withdrew from the study, one due to infection at the treatment site and the other due to an inflammatory reaction. This reaction was presumed to have been due to treatment application to an area greater than the original lesion. No recurrence of lesions was reported during the 9-month follow-up period. In uncontrolled BD trials, adverse events included marked local skin irritation requiring discontinuation of therapy, superinfection requiring antibiotics, and satellite lesions in adjacent sun-damaged areas [137,138].

**Comments** Imiquimod 5% cream appears to be an efficacious treatment for BD. Imiquimod 5% can be considered an alternative to surgery, either if the patient refuses surgical treatment or if the tumor's size or location makes surgical resection challenging. It can be used in lower limbs, particularly for large lesions on the lower extremity, such as the shin, where poor healing is of particular concern. Of note, if a patient does not respond to imiquimod with an inflammatory reaction, the medication should be stopped and alternative therapy should be chosen. There have been reports of invasive SCC and eruptive keratoacanthomatous carcinomas arising after imiquimod therapy for BD [139,140]. The dosing schedule and length of treatment require further evaluation in RCTs, as well as longer follow-up time.

#### **Ingenol mebutate**

Ingenol mebutate is a topical therapy recently approved for treatment of AK. It is a macrocyclic diterpene ester, derived from the sap of the plant *Euphorbia peplus*. Its effect is mediated through multiple pathways, including both rapid and direct keratinocyte cell death as well as by specific immune response via activation of protein kinase C delta and neutrophil-mediated oxidative burst [141–143]. It is provided in two concentrations, one for the face and scalp (0.015%, applied for three consecutive days) and one for the body and extremities (0.05%, applied for two consecutive days).

#### **Actinic keratoses (strength of recommendation: A)**

We identified three RCTs evaluating the use of ingenol mebutate in the treatment of AKs. The first RCT is a phase IIa study ( $n = 58$ ) that compared vehicle alone with the use of three different concentrations of ingenol mebutate gel (0.025%, 0.01%, and 0.05%) and two different treatment schedules: arm A treated on days 1 and 2, and arm B treated on days 1 and 8. Each patient had a representative lesion biopsied prior to, and following, treatment to evaluate for histologic clearance [144]. The second RCT that we reviewed was a multicenter, dose-finding study ( $n = 220$ ) [145]. This study also compared several different treatment protocols with vehicle alone: ingenol mebutate 0.025% gel for three consecutive days, 0.05% gel for two consecutive days, and 0.05% gel for three consecutive days. Patients were assessed at day 57 for clinical clearance of AKs.

The final RCT we reviewed was also a multicenter study comparing the use of vehicle alone with treatment ( $n = 547$ ) [146]: 269 patients applied ingenol mebutate 0.015% gel to a 25 cm<sup>2</sup> contiguous field on the scalp and/or face for three consecutive days and 222 patients applied ingenol mebutate 0.05% gel to a 25 cm<sup>2</sup> contiguous field on the body or extremities for two consecutive days. Clinical clearance was evaluated at 57 days. This study also completed an observational period of 12 months and documented recurrence/new lesions in previously treated fields.

**Benefits** In the RCT that examined the use of three different concentrations of ingenol mebutate on two different dosing schedules, it was shown that there was no statistically significant difference between treating on consecutive days (days 1 and 2) versus treating on days 1 and 8. The 0.05% gel was found to be the most effective, with 53 of 75 treated lesions clinically cleared at day 85 and 67% of patients with 80% or greater complete clinical lesion clearance [144].

In the second RCT reviewed, the best results at day 57 were seen with the 3-day course of 0.05% ingenol mebutate gel, with 54% of patients showing complete clearance and resolution of 60% of lesions documented prior to treatment. A 2-day course of 0.05% ingenol mebutate gel resulted in complete clearance rates of 44% and clearance of 44% of baseline lesions [145].

For the final RCT, patients who treated face and/or scalp with a 3-day course of 0.015% ingenol mebutate gel had a complete clearance rate of 42% and a median reduction in number of lesions of 83% at day 57. Treatment of trunk and extremities resulted in a complete clearance rate of 34% and a median percentage reduction in lesions from baseline of 75% at day 57. Observational 12-month follow-up of 146 patients with complete clearance at day 57 demonstrated that a mean of 85–87% of lesions in the treatment area at baseline were still clear at 12 months (torso and extremities vs face and scalp), but 50–53% of patients had developed one or more new lesions within the treatment area [146].

**Harms** The most commonly reported adverse effects were local site reactions such as erythema, flaking/scaling/dryness, and scabbing/crusting; these reactions were found to be most intense on day 3 to day 8; 98% of patients reported erythema on treatment day 3 [144,145]. The mean maximum composite local-skin-response score for both scalp/face and body/extremities on a scale of 0–24 was  $9.1 \pm 4.1$  versus  $1.8 \pm 1.6$  for placebo, and 98% of patients using ingenol mebutate reported local skin-response scores above baseline. Other common side effects included pain, pruritus, and irritation [146].

**Comments** Overall treatment with ingenol mebutate appears to be well tolerated with the additional benefit of a shorter treatment course than other patient-applied topical therapies.

The phase II RCT that evaluated lesions for histologic clearance at day 85 did not demonstrate a statistically significant difference between AKs treated with ingenol mebutate and those treated with vehicle only. Of lesions treated with vehicle, 42% demonstrated histologic clearance on day 85, suggesting that the initial biopsy may have had some effect upon the resolution of the lesion [144].

## Diclofenac

Diclofenac is a nonsteroidal anti-inflammatory drug formulated as a 3% topical gel in 2.5% hyaluronate sodium.

### Actinic keratosis (strength of recommendation: A)

We found one systematic review [147], and one phase IV, single-arm, open-label, 1-year extension study [148]. The systematic review conducted a meta-analysis of three RCTs ( $n = 364$ ) [149–151] and compared the results 30 days following 60 days of therapy with twice-daily diclofenac versus placebo gel [147]. The extension study examined patients 1 year after completing 90 days of treatment with twice-daily diclofenac, and examined the number of patients with 75% clearance or greater of their baseline AK lesion numbers ( $n = 76$ ) [148].

**Benefits** The meta-analysis of the three RCTs investigated in the systematic review [147] revealed that 40% of patients experienced complete lesion clearance at 30 days after the end of treatment, in comparison with 12% of patients treated with a placebo gel [147]. Complete lesion clearance rates (for two separate trials) 30 days after a 90-day treatment with diclofenac were 47% and 34%, in comparison with 19% and 18% for the placebo groups [152].

The phase IV, one-year extension study found that 91% of patients maintained clearance of at least 75% of their baseline lesions at 1-year follow-up, and 70% of patients had 75% or greater clearance of total cumulative lesions (baseline lesions plus any new AK lesions).

**Harms** The most common adverse effects reported after treatment with 3% diclofenac in 2.5% hyaluronic acid gel are pruritus, contact dermatitis, dry skin, rash, and scaling. Treatment is generally well tolerated [147].

**Comments** Treatment of AK using 3% diclofenac in 2.5% hyaluronic gel appears to be well tolerated, but with lower efficacy than other topical treatments reviewed. The lesion clearance rates in all of these studies were clinically assessed only, which may lead to overestimation. However, limited follow-up at 1 year does suggest that response is maintained following clinical clearance of lesions in the majority of patients.

### Bowen's disease (strength of recommendation: C)

We found no systematic reviews, RCTs, or case series that included more than 10 lesions. We found one case series, which treated two patients (each with one BD lesion) with 3% diclofenac in 2.5% hyaluronic gel twice daily for 90 days [153].

**Benefits** Both patients were clinically free of BD 10–12 months after treatment.

**Harms** One patient developed severe dermatitis and had to discontinue treatment after 80 days.

**Comments** Insufficient research has been conducted to establish the efficacy of this treatment for BD lesions. Given the high rates of SCC transformation of BD, and the low response rate of AK to diclofenac, it seems questionable and unethical for any further research to be conducted.

### Photodynamic therapy

PDT involves application of a topical photosensitizer, usually a porphyrin derivative, followed by activation by visible light. Visible light activates the photosensitizer in the presence of oxygen, creating reactive oxygen species, which selectively destroy the target

tissue. The two most commonly used photosensitizers are topical aminolevulinic acid (ALA) and MAL.

#### **Actinic keratoses (strength of recommendation: A)**

Although multiple reviews have been published on the use of PDT in AK, none of them includes a meta-analysis of the available data. Owing to the large number of RCTs examining the use of PDT in treatment of AK, we elected to review only those trials that contained at least 100 subjects. We examined 11 RCTs exploring the use of MAL- or ALA-PDT with activation by several different light sources (Table 35.4) [42–45,154–160].

**Benefits** Six RCTs investigating the use of MAL-PDT with a red light source found that 59–68% of patients experienced complete clearance of their AKs 3 months following treatment [154,155,159], and that 69–91% of individual lesions were cleared at 3 months [42–44,154,155,159] and 78–87% of lesions at 6 months [42,45]. Activation of MAL by 1.5 or 2.5 h of daylight resulted in clearance of 68% of AK at 3 months [156].

The percentage of patients with complete clearance at 3 months following ALA-PDT with red light activation was found to be 62–78% [157–159], and the percentage of AK with complete clearance at 3 months was 82–90% [158,159]. Activation of ALA by blue light resulted in 73% of patients with complete clearance at 3 months with 91% of individual AKs showing complete clearance [160].

Cosmetic outcomes with PDT were also measured in several of the RCTs reviewed [43–45,157,159], with 43–96% reporting “good” to “excellent” cosmetic results with ALA- and MAL-PDT.

**Harms** PDT is associated with a stinging or burning sensation during photoirradiation, as well as postprocedural erythema, edema, blistering, crusting, and other “phototoxic reactions” [42–45,154,155,157–160].

**Comments** PDT, using either ALA or MAL as a photosensitizing agent, has been highly successful in treating AK lesions, especially if they are widespread. Although the healing process is somewhat lengthy, it is comparable to the events experienced by patients following 5-FU and other topical regimens. It is an expensive treatment that requires a trained specialist and costly equipment to administer it and requires long office visits to complete. Despite this, several studies have reported patient preference for PDT over other topical treatments for AK [42–44].

#### **Bowen's disease (strength of recommendation: A)**

We found no systematic reviews, three RCTs, and several unblinded controlled trials. One RCT compared PDT using the photosensitizing agent MAL ( $n = 96$ ) with placebo-PDT ( $n = 17$ ), or with another standard therapy [53]. The standard therapy involved either cryotherapy or fluorouracil, as chosen by the treating investigator. The second RCT investigated 61 lower leg lesions to compare the efficacy of green light and red light wavelengths after incubation with 20% 5-ALA for 4 h [161]. The third RCT compared PDT using aminolevulinic acid ( $n = 20$ ) with 5% 5-FU ( $n = 20$ ) [109]. Compared with other treatment modalities for BD, there have been several prospective and retrospective trials, with greater than 50 patients, evaluating the use of ALA-PDT [162–165].

**Benefits** The complete response rate 3 months after treatment for lesions treated with MAL-PDT with red light was 93% in compari-

son with 21% for placebo-PDT-treated lesions [53]. At 12 months, the sustained clinical response for MAL-PDT was 80%, with a statistically significant difference between MAL-PDT and the combined standard therapy group ( $P = 0.04$ ). The recurrence rates for these treatments (1 year after treatment) were 15% for MAL-PDT and 50% for placebo-PDT [53]. Ninety-four percent of patients who experience pain related to MAL-PDT reported that it was of mild or moderate severity. Comparing red versus green light in ALA-PDT, lesions receiving red light showed a significantly greater clinical clearance rate, as determined by the dermatologist's examination (94% vs 76%;  $P < 0.002$ ), as well as a lower recurrence rate (6% vs 38%) in comparison with green light (odds ratio 0.13; 95% CI, 0.04–0.48) [161]. The authors attribute this difference to the reduced depth of tissue penetration by green light, postulating that peri-appendageal BDs (which may extend up to 3 mm in depth) may survive ALA-PDT using less-penetrating wavelengths. No ulceration, infection, scarring, or photosensitivity reactions were reported in either group. There was no significant difference in pain between the groups, and the majority of patients reported “none” to “moderate” pain [161]. In the third RCT, complete clearance 6 weeks after treatment was reported in 88% of lesions treated with ALA-PDT, in comparison with 67% in lesions treated with 5-FU [109]. After 12 months of follow-up, lesion recurrences reduced these rates to 82% for PDT and 48% for 5-FU (odds ratio 4.78; 95% CI, 1.56–14.62).

In the uncontrolled trials, including only studies with greater than 50 patients, evaluating the use of ALA-PDT, the clearance rates range from 84 to 96%, with recurrence rates ranging from 11 to 31% [162–165].

**Harms** Adverse effects of PDT include treatment-induced pain, requiring anesthesia, in up to 25% of lesions [166–168], skin fragility and dyspigmentation [168–170], permanent hair loss [170], toxic reactions to ALA cream [167], and photosensitivity reactions [166].

**Comments** PDT appears promising for the treatment of BD. While the first RCT was double blinded [49], investigators in the second RCT were not blinded to the type of light used [161], thus potentially introducing bias. Blinding was impossible in the third RCT [109] owing to the differences in treatment types being compared in the study. Although more objective outcomes, such as clinical clearance and recurrence, are less susceptible to bias related to lack of blinding, the validity of the results concerning treatment-related pain may be improved with blinding. The analyses for the first [53] and second RCTs [161] were not based on an ITT approach, since patients who discontinued treatment or were lost to follow-up were excluded from the final analysis – thus risking overestimation of the efficacy of the treatment and underestimation of recurrences. PDT can be considered an alternative nonsurgical treatment option for BD, especially when there are a large number of lesions.

### **What are the effects of intralesional or oral medication?**

#### **Oral retinoids**

#### **Actinic keratoses (strength of recommendation: B)**

We identified two RCTs investigating the use of etretinate in treatment of AKs, as well as one RCT examining the efficacy of acitretin in immunocompetent hosts in reducing the rates of nonmelanoma skin cancer, which reported reduction in AK as an additional

Table 35.4 Summary of RCTs of photodynamic therapy for AK.

First author, ref	Intervention	Comparators	Study design	Study population	Sample size (n)	Outcome measures	Main results	Adverse effects	Study quality: Randomization <sup>a</sup> Blinding <sup>b</sup> Statistical analysis <sup>c</sup>

<sup>a</sup> Adequate if clear description of method of randomization and concealment of allocation of randomization.<sup>b</sup> Adequate if assessors and participants were completely blinded to the study interventions.<sup>c</sup> Adequate if an intention-to-treat analysis was carried out.

outcome [171–173]. The two studies with etretinate used a crossover design and followed patients from 2 to 18 months. The acitretin study followed patients for 2 years while administering either placebo or acitretin 5 days per week.

**Benefits** Both RCTs for etretinate did not report the relevant outcomes, but instead recorded lesion size, the usefulness of which is dubious. Oral etretinate (Tegison) reduced the lesion size in 82–86% of patients, with improved overall grading of lesions in 89–100% of patients. Placebo resulted in lesion size reduction in only 4% of patients, with 17% of patients with improved overall grade following treatment [172,173].

Treatment with acitretin was not found to result in any significant difference in the number of AKs between those patients on active treatment and those receiving placebo [171].

**Harms** Dry lips and mouth may occur in a high proportion of patients using etretinate, although symptoms are alleviated with dose reduction. Mucocutaneous xerosis and alopecia were more frequent in patients receiving acitretin, as was hypertriglyceridemia [171]. Transient elevations of serum cholesterol and triglycerides, as well as one case of drug-related hepatitis, were reported with etretinate [173].

**Comments** The rates of reduction in lesion size and grading appear to be significantly better for etretinate than placebo. However, these results are based on outcome measurements that are limited in their usefulness. One should also be careful of crossover study designs, in which a considerable carry-over effect is likely. If insufficient time is allowed for the etretinate to wash out in the patients in whom etretinate was given before the placebo, then the effects of etretinate were probably confounding the results of the placebo.

While there is literature supporting the use of acitretin in treatment and prevention of AK in the solid organ transplant population, it is unclear if this evidence can be extrapolated to immunocompetent patients [174,175]. The data available to date do not support the use of systemic retinoids in the treatment or prevention of AKs in this group.

#### **Bowen's disease (strength of recommendation: C)**

We found no systematic reviews, RCT, or uncontrolled trials involving 10 or more subjects. Interestingly, there have been a few small uncontrolled case series investigating the use of acitretin or etretinate in treatment of BD in patients with chronic arsenicism [176–178].

**Comment** Oral retinoids cannot be recommended for treatment of BD, given that in some studies residual tumor cells were found in patients.

#### **Capecitabine**

##### **Actinic keratoses (strength of recommendation: B)**

Capecitabine is a prodrug of 5-FU and is the first oral chemotherapeutic agent approved by the FDA. It is used to treat primary and metastatic colon cancer as well as metastatic breast cancer. Inflammation and resolution of AKs have been reported in individual patients during treatment with capecitabine [179–181]. There are no RCTs examining the use of capecitabine in treatment of AKs, and only two small observational studies in the solid organ transplant population [182,183].

**Comment** At this time there is insufficient evidence available to recommend treatment with capecitabine for AK in immunocompetent patients.

#### **Bowen's disease (strength of recommendation: C)**

There are no studies or reports documenting the use of capecitabine in the treatment of BD.

#### **Interferon**

##### **Actinic keratoses (strength of recommendation: B)**

We found one double-blind, placebo-controlled, parallel-group RCT each for intralesional interferon alpha [184] and topical interferon gel (Intron A; interferon alpha-2b) [185]. The studies included 16–23 patients, with a posttreatment follow-up period of 1–2 months. No indication of complete cure on a per-patient basis was indicated.

**Benefit** High-dose interferon given intralesionally three times weekly for 2–3 weeks produced complete cure in 47–93% of the lesions treated [184]. No complete cures were produced with topical interferon gel, and only 9% of the lesions ( $n = 35$ ) showed marked improvement ( $>75\%$ ) [185].

**Comment** While high doses of intralesional interferon appear promising, it is impractical in the clinical setting and it is unlikely that the topical formulation will be of much benefit. However, intralesional interferon could be reserved for those patients who cannot use more conventional and economical therapies. In addition, adverse reactions, including myalgia, fever, and headaches, are common.

#### **Bowen's disease (strength of recommendation: C)**

We found one small unblinded quasi-RCT comparing topical 5-FU (5% cream) with intralesional interferon alpha-2b (1 000 000 units/injection) in the treatment of BD and AK [107]. We found one case report of one patient with multiple BD and AKs treated with oral isotretinoin at 1 mg/kg per day and interferon alpha-2a given subcutaneously  $3 \times 10^6$  U three times per week [186].

**Benefit** In the small trial, the 5-FU group showed 100% clinical clearance, whereas the interferon group showed 90% clinical clearance at the 8-week assessment. However, the study did not differentiate between BD and AK [107]. In the case report, although the patient had clinical improvement of her lesions, further treatment was required [186].

**Comment** Intralesional interferon may be a good option for BD in those not responsive to more conventional and economical therapies. Systemic interferon use has not been studied, and side effects are common with flu-like symptoms.

#### **Bleomycin**

There is one anecdotal report of the successful use of intralesional bleomycin in the treatment of BD [187].

#### **What are the effects of application of sunscreen?**

##### **Actinic keratoses (strength of recommendation: A)**

Given the pathophysiology of the development of AKs and BD is related to UV exposure, the use of topical photoprotection in preventing the development of nonmelanoma skin cancers has been

studied. We found three randomized control trials evaluating the use of routine sunscreen in the prevention of AKs [188–190]. There have been nonrandomized control trials in the transplant population showing the use of sunscreen (sun protection factor (SPF) >50, high-UVA) also reduces the development of AK, as well as non-melanoma skin cancers [191].

### Benefit

In an Australian study of 588 patients, those who used daily broad-spectrum UVA–UVB of SPF 17, applying 1.5 ml to the head/neck as well as 1.5 ml to each forearm/hand, over a 7-month period had a fewer number of new AKs compared with the placebo group (difference, 0.7; 95% CI, 0.2–1.3) with an 81% compliance rate [188]. The Nambour Skin Prevention Trial evaluated the use of daily SPF 15 plus sunscreen and oral betacarotene 30 mg supplementation in an Australian population of 1621 study participants over 4.5 years in the prevention of AKs, as well as nonmelanoma skin cancer [190,192]. In the daily sunscreen group in the first 2 years of the study, there was a 20% increase in solar keratosis compared with a 57% increase in solar keratosis in the placebo group ( $P < 0.05$ ) [190]. For the last 2 years of the study, the difference was not significant. The use of daily SPF 29 in a Texas population had a 36% reduction ( $P$ -value 0.001) in annual AKs over patients who were in the placebo group over a 2-year period (total study population of 50 people) [189]. In this study, the effect was greatest for lighter skinned individuals with more AKs at baseline, which are patients at higher risk for developing AKs.

### Harm

The most common side effects was burning of product, especially when coming in contact with eyes [189]. Other side effects included acneiform eruptions. There was no mention of allergic or irritant contact dermatitis in these studies.

### Comment

The use of sunscreens has been shown to decrease the development of AK. However, sunscreen use needs to be on a daily basis to have such effects. There have been reports of allergic and irritant reactions to UV filters contained in sunscreens. Given that vitamin D is formed within the skin through the action of UV radiation, monitoring of vitamin D status is important in patients who strictly avoid the sun and are diligent about wearing sunscreen. In both immunocompetent and immunosuppressed patients, the use of sunscreens with broad-spectrum UVA and UVB protection is recommended, in combination with the use of photoprotective clothing, such as wide-brimmed hats. Given that many withdrawals from the study were due to either misconception that the sunscreen was working or the dislike of the sunscreen, education and choosing a product that patients will use daily is essential.

### Implications for clinical practice: spontaneous regression rates and future studies

As discussed in the “Background” section, the prognosis for patients with AKs without treatment is confounded by the spontaneous regression rate. A study in Queensland reported a spontaneous regression rate of 85% (95% CI, 75–96%) in people with prevalent AK (AK diagnosed on a person during their first examination) and 84% (95% CI, 72–96%) in persons with incident AK (AK appearing for the first time during the study) [31]. Such spontaneous regression rates emphasize the need for a comparison arm in order for the study to be well designed. Moreover, while most studies utilize the disappearance of AKs as the endpoint of the study, the more relevant clinical outcome is to determine whether the therapy in question really reduces the risk of SCC in the long term.

## Key points

### Actinic keratoses

- We found good evidence to suggest that cryotherapy, PDT, topical 5-FU, ingenol mebutate, and imiquimod may be beneficial in the treatment of AK.
- Fractional photothermolysis, radiotherapy, and topical retinoids are not appropriate treatments for AK.
- Different modalities of treatment may be preferred in spot treatment of discrete lesions versus field treatment for diffuse disease.
- The evidence supporting the efficacy of most therapies is insufficient or limited.
- It is still unclear whether any of the treatments reduce the incidence of invasive SCC – the outcome of most importance.
- Studies were not consistent in choosing their units of analysis. Some used the number of lesions, others used persons cleared, and others used both as their units of analysis. Readers should determine which unit is most relevant to their practice.
- The use of daily broad-spectrum sunscreen with photoprotective clothing should be encouraged in all patients because it reduces the development of AKs.
- Given the high rate of spontaneous resolution of AKs over time, debate still exists on whether all patients need treatment.

### Bowen's disease

- The evidence for treatment of BD is generally of poor quality, with few RCTs.
- The choice of therapy in BD should take into account the location of the lesions, particularly the lower legs and the digits, where healing may be complicated.
- ED&C, PDT, and cryotherapy are acceptable first-line treatments for BD, given the available evidence.
- ED&C may be superior to cryotherapy for lower leg lesions.
- Radiotherapy might be an option for larger lesions where other therapies are not an option.
- The topical therapies 5-FU and imiquimod have shown efficacy but might have poorer outcomes compared with surgical approaches.
- There is no evidence to support the use of topical diclofenac in the treatment of BD.
- There have been no studies on the use of dermabrasion, topical retinoids, or topical ingenol mebutate in the treatment of BD.
- There appears to be good evidence for the superior efficacy of red light over green light in PDT with ALA.

## Acknowledgments

We thank Aditya K. Gupta, Jenna E. Bowen, Elizabeth A. Cooper, Seaver L. Soon, and Peterson Pierre.

## Other useful resources

For further information on the treatment of AK or BD, the British Association of Dermatologists publications on the management of BD [193] and AK [194] may also be helpful.

# Kaposi sarcoma

Whitney A. High

Department of Dermatology, University of Colorado Health Sciences Center, Denver, CO, USA

## Background

In 1872, Moritz Kaposi, a Viennese dermatologist, first-described Kaposi sarcoma (KS) as an “idiopathic multiple pigmented sarcoma of the skin.” [1] For more than a century the disease existed as a relatively obscure condition, affecting chiefly the legs of older men of eastern European, Mediterranean, and/or Jewish descent.

In 1981, KS “re-emerged” as a disease of increased incidence and importance, occurring in association with acquired immunodeficiency syndrome (AIDS) [2]. Another major advance in the subject occurred in 1994, when human herpesvirus 8 (HHV8) was implicated in the etiology of the disorder [3]. To date, HHV8 infection has been demonstrated in essentially all forms of KS (whether “AIDS related” or not), and it is believed this infection is requisite to development of disease, although a permissive environment of immunosuppression is also likely involved.

Four clinical variants of KS are widely recognized:

- **Classic KS.** This affects chiefly older men of Mediterranean or Jewish heritage, with peak incidence after the sixth decade. Classic KS presents as purple–blue plaques upon the lower legs (Figure 36.1). The disease is often largely indolent, but it may progress over years. Morbidity in classic KS is typically limited, but it may include also venous stasis and chronic lymphedema. Mortality is truly exceptional. It has been reported that up to a third of patients with classic KS may develop a second malignancy; in particular, non-Hodgkin lymphoma [4].
- **Epidemic (AIDS-related) KS.** This is the most common form of KS in the USA, and in the developed world. In fact, early in the HIV/AIDS epidemic, it was thought that KS (Figures 36.2 and 36.3) occurred up to 20 000- to 50 000-fold more often among AIDS patients than the general population [5,6]. Epidemic (AIDS-related) KS is often more aggressive than most other forms of the disease, and patients may present with extensive disease. KS remains an AIDS-defining illness. The presence of decreased CD4 counts is the most important prognostic factor in the development of epidemic (AIDS-related) KS, and in some series less than 10% of HIV-infected patients who develop KS have a CD4 count  $>500/\mu\text{L}$  [7]. However, in a small number of patients even persistent KS may present in the absence of relatively higher CD4 counts [8]. Decades ago, oral KS was the first

recognized clinical manifestation of AIDS in about 25% of patients, whereas today, with widespread use of highly active antiretroviral therapy (HAART), KS is seen relatively infrequently in AIDS patients (2–3% of patients).

- **Endemic (African) KS.** This occurs in sub-Saharan Africa, mostly affecting HIV-negative women and children (Figure 36.4). Endemic (African) KS may follow an indolent or aggressive course. In general, endemic (African) KS affects lymph nodes more often than classic KS, but other etiologic factors, beyond HHV8 infection, are not well understood. Some investigators have implicated a reduced wearing of shoes, with resultant traumatic inoculation of the feet by volcanic soil particles leading to lymphatic obstruction, to the development of endemic (African) KS, and even classic KS as well, but this remains speculative [9,10].
- **Iatrogenic/immunosuppression-related KS.** Transplant recipients placed on immunosuppressive medications, as well as others placed on similar medical regimens, are at increased risk for iatrogenic KS. The incidence of KS may be approximately 84-fold higher among organ transplant patients in comparison with the general population [11]. Most iatrogenic KS occurs at least 1–2 years after immunosuppressive medications are initiated [12]. While an aggressive course, with visceral involvement, can occur with iatrogenic KS, withdrawal of the immunosuppressive agent(s) may often yield disease regression and remission. Furthermore, the specific immunosuppressive agent(s) employed impacts risk. Sirolimus, in addition to immunosuppressive effects, possesses antineoplastic properties as well, and the agent has not been associated with the same elevated risk of KS seen in other immunosuppressive medications; in fact, it may even be employed in the management of iatrogenic KS [13]. Iatrogenic KS occurs more often among the same populations that are at risk for classic KS, suggesting the etiology may be multifactorial.

## Incidence/prevalence

The incidence of KS varies with the clinical subtype.

- Classic KS is rare, but is most common in older men, with an M:F ratio of up to 15:1. Peak onset occurs at 50–70 years of age.

Figure 36.1 Classic KS, with edema of the left leg.

Figure 36.3 Extensive AIDS-related KS.

Figure 36.2 KS affecting the hard palate in a patient with AIDS.

The disease is particularly prevalent in Israel and the Mediterranean, including southern Europe. In fact, in southern Italy, the incidence rate of classic KS range may be as high as 24–30 cases per million in men, and five to eight cases per million in women [14].

- Epidemic AIDS-related KS is the most common form of KS, worldwide. In the USA, the incidence of AIDS-related KS reached its zenith in 1989, when it was the most common AIDS-related neoplasm, and its incidence has declined since then, particularly with widespread adoption of HAART [15]. The incidence among men outside of the San Francisco area manifested a profound decrease, dropping from 7.9 to 1.6 cases per 100 000 [16]. Similarly, a European multicenter cohort study of nearly 10 000 HIV-positive patients reported an estimated annual reduction of 39% between 1994 and 2003 for epidemic (AIDS-related) KS among patients receiving HAART [17]. Overall, the incidence of KS among patients with HIV is less than 10% of the incidence reported in 1994.

Figure 36.4 Endemic (African) KS.

- Endemic (African) KS is a relatively common tumor in sub-Saharan Africa, and there has been an increased incidence and a narrowing of the M:F ratio over time, moving from a historic ratio of 19:1 (1960–1971) to the more modern ratio of less than 2:1 (1991–1997) [18]. In fact, in many parts of Africa, KS is now the most common cancer in men and the second most common in women [19].

- Iatrogenic KS among transplant recipients has been estimated at 8.8 per 100 000 person-years in the USA, with most cases occurring in the first 2 years after transplantation, and the risk of KS increases steadily with recipient age ( $P = 0.001$ ) [20].

### Etiology

An infective etiology for KS was long suspected, but a milestone in understanding came in 1994, when Chang *et al.* identified sequences of HHV8 DNA, within tumor material [3]. Since that time, the virus has been detected in virtually all KS specimens, regardless of subtype, but has been absent from uninvolved skin. The viral genome encodes proteins that are homologous with human oncoproteins and have the potential to induce cellular proliferation and inhibit apoptosis. The presence of HHV8 appears requisite to development of KS, but the role of other permissive cofactors, such as immunosuppression, other cytokines, and HIV, is still being investigated and debated.

As a malignancy, it was long presumed that KS was caused by the clonal expansion of a single endothelial cell, but recent evidence may suggest otherwise. For example, the cell of origin is still unproven, and expression of multiple immunohistochemical markers among KS cells, including factor VIIIa, smooth muscle actin, CD68, and CD14, as well as lymphatic markers, such as D2-40, in addition to common vascular markers of CD31 and CD34, may also be interpreted to suggest the origin is a pluripotent mesenchymal progenitor cell [21,22].

Similarly, data from a series of patients with multiple lesions of KS showed that nearly 80% of the tumors were polyclonal in nature, engendering speculation that “metastatic” KS may not be truly metastatic (in the strict sense), but may be multifocal, arising independently at various sites [23].

### Diagnosis/histology

The diagnosis of KS is typically made based upon clinical suspicion, and then confirmed with a biopsy and histopathologic analysis. While the fundamental qualities of a malignant spindle cell neoplasm are common to all forms KS, clinical circumstances, as well as the temporal course of the lesion, will clearly impact the histologic findings in cutaneous disease [24].

- **Patch stage.** The earliest phase in the evolution of typical cutaneous KS, patch stage disease, also presents the greatest degree of diagnostic difficulty owing to the subtle nature of the findings. Often, the dermis only appears only slightly hypercellular, with subtle and slit-like or jagged vascular spaces present upon close inspection. The protrusion of newly formed rudimentary vascular structures into the lumen of larger vascular channels results in a “promontory sign.” Proliferating vessels may dissect the collagen, and often there are a varied number of extravasated erythrocytes and hemosiderin-laden macrophages. Background inflammatory cells, mostly lymphocytes and plasma cells, may be present.

- **Plaque stage.** This is accompanied by greater cellularity and perhaps even extension of neoplastic process into the subcutis. Atypical spindled cells are arranged in haphazard fascicles. Mitotic figures may be present, and extracellular perioic acid Schiff-positive hyaline globules, thought to represent fragmented and decaying erythrocytes, may be noted [25]. Dissecting vascular channels with central erythrocytes exist in the dermis, and an inflammatory infiltrate rich in plasma cells is common.

- **Nodular stage.** Nodular disease usually results in marked dermal expansion of atypical spindled cells arranged in fascicles (Figure 36.5). These spindled cells are monomorphic and atypical in appearance. Mitotic activity among the cells is not uncommon. Hyaline globules, also seen in plaque-stage disease, are typically rather numerous in nodular KS. At the periphery of nodular lesions there are often dilated and congested vascular spaces.

Other recognized and described variants of KS, beyond the scope of this discussion, but more germane to a text on dermatopathology, include hyperkeratotic, keloidal, micronodular, pyogenic granuloma-like, ecchymotic, and intravascular forms [24].

Immunohistochemical stains that may prove useful in confirming a histologic assessment of KS include use of antibodies directed at the alleged endothelial/lymphatic origin of the spindled cells, such as CD31 (platelet/endothelial cell adhesion molecule, PECAM1), CD34 (a hematopoietic progenitor cell surface protein), D2-40 (podoplanin, a cell surface marker of lymphatic endothelium), and FLI1 (Friend leukemia virus integration 1, a member of the ETS family of DNA-binding transcription factors). **Figure 36.5** Histologic and immunohistochemical analysis of nodular KS: (a) stained with H&E, shows atypical spindled cells and extravasated erythrocytes and pink hyaline globules (arrow). (b) stained with an immunohistochemical marker for HHV8, shows strong and aberrant positivity among the atypical spindled cells (arrow).

investigation of these four antibodies (CD31, CD34, D2-40, and FLI1) strongly and diffusely stained tumor cells in 75%, 92%, 67%, and 92% of AIDS-related cases, and 58%, 92%, 67%, and 75% of non-AIDS-related cases, respectively [26]. Additionally, a commercially available monoclonal antibody directed against HHV8, for use on formalin-fixed, paraffin-embedded tissue, has been available since 2004. One such clone, directed against the virus latency-associated nuclear antigen of HHV8, has demonstrated high sensitivity and specificity for all clinical subtypes and tumor stages of KS, and is of great utility, especially in subtle patch-stage disease [27].

Prognosis

The prognosis for KS varies depending upon the clinical subtype, the extent of tumor and/or organ involvement, and the overall general medical condition of the patient.

- Classic KS usually follows a rather indolent course that spans years or decades. Complications include venous stasis, lymphedema, and verrucous and/or hyperkeratotic qualities to the epidermis overlying KS lesions. Admittedly, many of these conditions, to one degree or another, are not unexpected upon the lower legs of elderly persons with circulatory issues (even absent KS). It is widely held that persons with classic KS often die “with the disease,” rather than “of the disease.”
- Epidemic (AIDS-related) KS may be a disseminated and fulminant disease. The tumor extent (T), immune status (I), and severity of systemic illness (S) are all expected prognostic determinants. To this end, in the pre-HAART era, a TIS staging classification was proposed and prospectively validated (Table 36.1) [28]. Even in the HAART era, only minor alterations of these prognostic factors are proposed. For example, CD4 count of <200 cells/ $\mu$ L and tumor extension are no longer negative prognostic factors, but a CD4 count of <100–150 cells/ $\mu$ L and associated systemic

diseases are important considerations in patients taking HAART [29,30].

- Endemic (African) KS may run an indolent course similar to that of classical KS, with nodules and plaques occurring in association with limb edema. In particular, some cases of lymphadenopathic endemic (African) KS occurring in children in Africa may follow an aggressive clinical course, with an adverse prognosis [31].
- Iatrogenic KS may often substantially improve or even regress following reduction or removal of immunosuppressive medications [32,33].

Therapeutic goals

Similar to prognosis, the goals of therapy vary with the clinical form of disease, the extent of disease, and the general medical health of the patient with KS.

- Classic KS often responds quite well to local interventions, although the recurrence rate is high.
- Epidemic (AIDS-related) KS is improved significantly by the addition of HAART, which prolongs overall survival and is associated with an 80% reduction in the risk of death [34], prolongs the time to treatment failure [35], and prolongs the survival of patients with pulmonary KS who receive also chemotherapy [36]. It is unclear exactly how HAART induces regression of KS, but potential mechanisms are thought to include immune reconstitution [37], general improvement in the immune status, and perhaps even direct anti-angiogenic and antineoplastic effects [38].
- Endemic (African) KS usually responds well to systemic interventions, except for aggressive lymphadenopathic forms.
- Transplantation-related or immunosuppression-related KS often regresses after the reduction or cessation of immunosuppressive medications.

Relevant outcomes

Complete disappearance of the disease is the most obvious relevant outcome, but it is not always achieved or reported in trials regarding the treatment of KS. A reduction in the number and/or size of lesions, lesion flattening, and reduction in pigmentation may represent other measured endpoints. The subjective nature of many assessments is a shortcoming in the comparison of treatments. To this end, AIDS Clinical Trials Group (ACTG) criteria were developed for use in clinical trials (Table 36.2) [39]. In fact, modified variants of the original ACTG criteria are still currently employed in the most recent clinical trials [40]. Furthermore, improved cosmesis, while markedly subjective, is also an important endpoint for affected patients, particularly with regard to localized interventions. Lastly, palliation of tumor-related symptoms, such as edema or pain, is another endpoint that, while highly subjective, is valued by patients.

Methods of search

We searched Medline from 1966 to December 2012. We first performed a highly sensitive search using the truncated term “Kaposi\*,” which generated over 10 000 abstracts. We then performed a more specific Medline search using “sarcoma, Kaposi” (MeSH terms) or “Kaposi’s sarcoma” (text word), combined with the following interventions: alitretin, antiretroviral therapy, anthracycline, antiangiogenic agent, bleomycin, chemotherapy, cidofovir, gemcitabine, highly active antiretroviral therapy, interferon (IFN), intralesional therapy, intralesional vinblastine, intralesional vincristine, paclitaxel, radiotherapy, retinoids, vinca-alkaloid, vincristine,

Table 36.1 ACTG staging classification.

Good risk (0): all of the following		Poor risk (1): any of the following
Tumor (T)	Confined to skin and/or lymph nodes and/or minimal oral disease <sup>a</sup>	Tumor-associated edema or ulceration
		Extensive oral KS
		Gastrointestinal KS
		KS in other nonnodal viscera
Immune system (I)	CD4 count $\geq 200 \times 10^6/L^b$	CD4 count $< 200 \times 10^6/L^\ddagger$
Systemic illness (S)	No history of opportunistic infections or thrush	History of opportunistic infections and/or thrush
	No “B” symptoms <sup>c</sup>	“B” symptoms present
	Performance status $\geq 70\%$ (Karnofsky)	Performance status $< 70\%$
		Other HIV-related illness (e.g., neurological disease, lymphoma)

<sup>a</sup>Minimal oral disease is KS, without a nodular appearance, confined to the palate.  
<sup>b</sup>Subsequent evidence suggests CD4 count of  $150 \times 10^6/L$  may be a superior discriminator.  
<sup>c</sup>“B” symptoms are unexplained fever, night sweats, >10% involuntary weight loss, or diarrhea persisting for more than 2 weeks.

**Table 36.2** ACTG response criteria.**Complete response (CR)**

The absence of any detectable residual disease, including tumor-associated edema, persisting for at least 4 weeks

**Clinical complete response (CCR)**

In patients in whom pigmented (brown or tan) macular skin lesions persist after apparent CR, biopsy of at least one representative lesion is required to document the absence of malignant cells. In patients known to have had visceral disease, an attempt at restaging with appropriate endoscopic or radiographic procedures should be made. If such procedures are medically contraindicated, the patient may be classified as having CCR

**Partial response (PR)**

The absence of new cutaneous or oral lesions, new visceral sites of involvement, or the appearance or worsening of tumor-associated edema or effusions, in addition to at least one of the following:

- A 50% or greater decrease in the number of all previously existing skin lesions (skin, oral, measurable or evaluable visceral disease)
- A 50% decrease in the size of lesions (includes a 50% decrease in the sum of the products of the largest perpendicular diameters of bidimensionally measurable marker lesions and/or complete flattening of at least 50% of the lesions; that is, 50% of previously nodular or plaque-like lesions become macules)
- In those patients with predominantly nodular lesions, flattening to an indurated plaque of 75% or more of the nodules
- Patients with residual tumor-associated edema or effusion who otherwise meet the criteria for CR

**Stable disease (SD)**

Any response not meeting the criteria for progression or PR

**Progressive disease (PD)**

An increase of 25% or more in the size of previously existing lesions, and/or the appearance of new lesions or new sites of disease, and/or a change in the character of 25% or more of the skin or oral lesions from macular to plaque-like or nodular. The development of new or increasing tumor-associated edema or effusion is also considered to represent disease progression

vinblastine, taxane, paclitaxel, retinoids, retinoic acid, zidovudine. We also searched the Cochrane Central Register of Controlled Trials and Database of Systematic Reviews using the search terms “Kaposi\*” and “Kaposi’s sarcoma.”

## Questions

### What are the effects of local treatments commonly employed in management of Kaposi sarcoma (radiotherapy, topical alitretinoin, topical imiquimod, intralesional interferon and intralesional chemotherapy)?

#### Radiotherapy

There are numerous case reports and case series employing radiotherapy as local intervention for classic KS, and it is a radiosensitive condition. In most of these publications the patients were treated with either local or extended-field radiotherapy, or local electron beam. High response rates (80–90%) were reported; however, response criteria were not always well stated, and/or varied among reports.

In epidemic (AIDS-related) KS there are a few published trials comparing different radiotherapy regimens.

- One trial compared 71 lesions of biopsy-proven KS, occurring in 14 AIDS patients (seven taking zidovudine, but none taking HAART) [41]. KS lesions were randomized to receive either 8 Gy in one fraction, 20 Gy in 10 fractions, or 40 Gy in 20 fractions. The trial was not blinded and randomization criteria were not stated. Results were assessed on an intention-to-treat (ITT) basis. A complete response was the principle endpoint, defined as resolution of all palpable tumor in the radiation field. Improved results were observed in lesions dosed with either 40 Gy given in 20 fractions, or 20 Gy given in 10 fractions, when compared with those dosed with 8 Gy in a single fraction (83% and 79% vs 50%). Median recurrence times were improved as well (43 and 26 weeks vs 13 weeks). Adverse events were more common in lesions treated with 20 or 40 Gy than in those treated with a single dose of 8 Gy.
- A second trial involved the comparison of conventional fractionated radiotherapy with a hypofractionated regimen [42]. Sixty-five evaluable lesions in 47 patients with AIDS-related cutaneous KS were randomized to receive either a standard regimen of 24 Gy in 12 fractions (35 sites), or 20 Gy in five fractions (30 lesions). Some patients expired prior to irradiation, but the treatment arms were similar with regard to gender, Eastern Cooperative Oncology Group performance score, anatomic site, and use of concurrent antiretroviral therapy. With regard to the response observed (complete or partial) or the mean time to a maximum objective response, there were no significant differences among the two treatment arms, and skin toxicity (acute or chronic) was also equivalent.

#### Drawbacks

In the earlier trial, toxicity was graded using the Radiation Therapy Oncology Group scoring system. Grade 1 acute toxicity (skin erythema, dry desquamation, or alopecia) was seen in 3 of 24 (12%) patients who received 8 Gy, 11 of 24 (46%) patients who received 20 Gy, and 22 of 23 (96%) patients who received 40 Gy. Late skin toxicity, again not to exceed grade 1 (slight hyperpigmentation or alopecia), occurred only in patients receiving 40 Gy (six of 23).

In the later trial, where a hypofractionated dose of 20 Gy was compared with a conventional fractionated dose of 24 Gy, skin toxicity was statistically equivalent among the groups, the investigators advised caution when employing the hypofractionated regimen in patients with severe lymphedema, as four patients receiving this latter regimen developed ulceration or necrosis.

#### Comments and implications for practice

Radiotherapy, either in a local or extended field, and either highly fractionated or hypofractionated, yields a high response rate in the treatment of KS. In AIDS patients this intervention is still widely employed, especially to control oral disease. The rate of complete response and the duration of control may be improved with higher dose and highly fractionated radiotherapy; however, shorter treatment regimens are resource sparing, and benefit patients in health systems that are unable to bear the costs of prolonged treatment. Also, larger doses per fraction in radiotherapy may result in increased toxicity. Additionally, in the era of HAART, a decision to treat may also be influenced by use of concurrent antiretroviral therapy.

#### Topical alitretinoin

Alitretinoin (9-*cis*-retinoic acid) gel is a retinoid receptor pan-agonist that was pursued about a decade ago as treatment of

cutaneous KS. A Cochrane review examined two trials of topical alitretinoin used as treatment in patients with epidemic (AIDS-related) KS [43], but the results could not be combined owing to heterogeneity. Without belaboring details, both trials indicated safe and effective use, and irritation was the major drawback, but the overall response rates were modest [44,45]. While approved for this indication, the drug is not in widespread clinical use for treatment of KS. While occasional case reports of success and failure continue to be published, no organized clinical investigation of this agent for treatment of KS has transpired since 2003 [46].

### Intralesional interferon

Because of its antiviral effect, intralesional IFN- $\alpha$  has been investigated for use in the treatment of KS.

- A small clinical investigation examined use of intralesional and perilesional IFN- $\alpha$  (50 000 international units twice weekly for 4–6 weeks) to treat non-AIDS-related KS in 12 patients, and compared this regimen with an untreated lesion in the same patient. An additional treatment arm investigated use of IFN- $\alpha$  in combination with interleukin-2 in eight additional patients, again comparing the combined intervention with an untreated lesion in the same patient [47]. All the treated lesions yielded complete resolution, while all the untreated lesions remained unchanged, and the observed clinical cure was then verified histologically. Investigators concluded that intralesional IFN- $\alpha$  is an effective treatment for non-AIDS-related KS.
- In a small study of 17 patients with epidemic (AIDS-related) KS who were receiving zidovudine (500 mg/day), up to five KS lesions per patient were injected with IFN- $\alpha$  (1 million units three times weekly for 6 weeks) and compared this therapy with another lesion in the same patient that was injected with sterile water [48]. Three patients were lost to follow-up and three patients were injected only with IFN- $\alpha$  because just one lesion was present. In brief, a complete response was seen in 41 of 54 (76%) treated lesions, in comparison with three of 11 (27%) lesions injected with sterile water. ITT results were neither provided nor calculable. On biopsy, two of 15 (13%) lesions injected with IFN- $\alpha$ , and one of two lesions injected with sterile water but for which a clinical response was observed, were found to have microscopic evidence of persistent KS.

### Drawbacks

Patients placed upon systemic IFN- $\alpha$  experienced flu-like symptoms. Local pain and inflammation at the injection site was common. Published regimens required two to three visits per week for up to 6 weeks.

### Comments

Intralesional IFN- $\alpha$  is not often used in clinical practice for epidemic (AIDS-related) KS, especially in the era of HAART (see below).

### Intralesional chemotherapy

In the literature of oral medicine, a small randomized trial compared intralesional vinblastine and 3% sodium tetradecyl sulfate (STS), a sclerosing agent, as a treatment for oral epidemic (AIDS-related) KS [49]. A similar reduction in tumor mass was observed for both agents, and it was concluded that both agents were effective in controlling the condition. STS was associated with a lower cost and greater ease of use.

### Comment

Intralesional vinblastine (0.1–0.2 mg/mL) has been used in several case series of patients with cutaneous epidemic (AIDS-related) KS, with reported response rates ranging from 60 to 92%. In particular, intraoral lesions of epidemic (AIDS-related) KS has been treated with particular efficacy using this agent.

### Topical imiquimod

#### *Classic and endemic (African) Kaposi sarcoma*

Because KS can be treated with intralesional IFN- $\alpha$ , it was hypothesized that imiquimod, a topical immune response modifier that induces endogenous production of IFN and related substances, would be efficacious in treating the disorder. In one prospective, open-label, single-center, phase I to phase II trial, topical imiquimod 5% cream was utilized in the management of classic or endemic (African) KS skin lesions in HIV-negative patients [50]. Topical imiquimod 5% cream was applied under occlusion three times a week for 24 weeks in 17 enrolled patients. Results were analyzed in ITT format, and there were eight (47%) with an overall clinical response (two complete, six partial), while progression was noted in six patients.

**Drawbacks** Side effects included local itching and erythema, reported in nine patients (53%).

**Comments** This trial was not randomized, it was not blinded, and it was not placebo controlled. It was restricted to a small number of patients. While topical imiquimod 5% cream was efficacious in only about one-half of patients with classic and endemic (African) KS, it was generally well tolerated and it is widely available to the practicing dermatologist.

### Is interferon- $\alpha$ an effective systemic treatment for Kaposi sarcoma?

#### *Classic and endemic (African) Kaposi sarcoma*

No randomized clinical trials were found. Only case reports and small case series were found in the literature.

### Comment

Data are insufficient to draw firm conclusions regarding the effectiveness of systemic IFN- $\alpha$  in the treatment of classic or endemic KS.

### Epidemic (AIDS-related) Kaposi sarcoma

Phase II trials demonstrated the efficacy of high-dose IFN as a monotherapy for epidemic (AIDS-related) KS. Side-effects of such treatment included dose-related phenomena, such as flu-like symptoms, but gradual dose escalation ameliorated this toxicity [51,52].

Multiple phase II trials performed subsequently examined the treatment of epidemic (AIDS-related) KS using a combination of IFN- $\alpha$ , at low or intermediate doses, with zidovudine. Relatively low doses of IFN- $\alpha$  (in comparison with those used as monotherapy) proved efficacious if combined with zidovudine, and suggested relative efficacy, even in patients with CD4 counts <200/ $\mu$ L, a population that had responded poorly to high IFN alone [53,54]. A similar phase II trial of 68 patients examined the efficacy of low and intermediate doses of IFN- $\alpha$ -2b in combination with didanosine (ddI), and a 40% response was observed in the low-dose group (95% confidence interval [CI], 24–58), with a 55% response rate in

the intermediate-dose group (95% CI, 36–72) [55]. Median duration of remission was 110 weeks in both groups.

### Comments

The advent of HAART has altered substantially the clinical course of epidemic (AIDS-related) KS. The effectiveness of IFN combined with HAART is unknown. Use of zidovudine or ddI alone is no longer standard therapy for HIV infection.

## What are the effects of systemic chemotherapy employed in Kaposi sarcoma?

### Classic Kaposi sarcoma

We found one randomized but unblinded study comparing oral etoposide with intravenous vinblastine in the treatment of classical KS in elderly Mediterranean patients [56]. Sixty-five patients were assigned randomly to receive either oral etoposide (60 mg/m<sup>2</sup> on days 1–3 during the first course; 60 mg/m<sup>2</sup> on days 1–4 during the second course; and 60 mg/m<sup>2</sup> on days 1–5 during the third course; courses were recycled every 3 weeks) or intravenous vinblastine (3 mg/m<sup>2</sup> weekly for 3 weeks, and then 6 mg/m<sup>2</sup> every 3 weeks). With a median follow up of 38 months, there were no statistically significant differences in number of complete or partial responses, in the duration of response, or in survival. Side effects of both agents were limited, although myelotoxicity was more evident in those patients receiving vinblastine.

### Comment

Neither agent is used often to treat classic KS.

### Epidemic (AIDS-related) Kaposi sarcoma

A Cochrane systematic review of treatments for AIDS-KS [43] included two randomized and unblinded studies comparing pegylated liposomal doxorubicin (PLDox) with standard treatment regimens in patients with advanced KS [57,58]. Randomization methods were not detailed for either study, and analysis occurred on an ITT basis. Meta-analysis of these two studies yielded a total of 499 patients treated with PLDox, versus a standard KS regimen using either doxorubicin, bleomycin, and vincristine (ABV, first trial), or bleomycin and vincristine (BV, second trial). No participant, in either study, was receiving HAART. The relative risk (RR) of death was not significantly different for either of the two treatments (RR, 1.26; 95% CI, 0.83–1.91), and the response to PLDox was superior to that of the ABV/VB in each trial (RR, 2.16; 95% CI, 1.68–2.78). Adverse events were reported in different ways and could not be analyzed together, but serious adverse events did not differ significantly between the PLDox (RR, 0.97; 95% CI, 0.91–1.04) or the standard regimens (RR, 1.01; 95% CI, 0.96–1.06). Fewer withdrawals occurred in the PLDox-treated group (RR, 0.57; 95% CI, 0.48–0.68), but more opportunistic infections were observed (RR, 1.42; 95% CI, 1.12–1.80).

Another phase III trial of pegylated liposomal daunorubicin (PLDaun) versus a reference regimen of ABV in advanced epidemic (AIDS-related) KS was not included in the meta-analysis because it did not report results on an ITT basis [59]. In brief, this trial that could not be integrated to the meta-analysis was a prospective, randomized, phase III trial, including 232 patients who were randomly assigned to receive PLDaun 40 mg/m<sup>2</sup> or a combination ABV regimen administered intravenously every 2 weeks. Treatment was continued until a complete response (CR) or unacceptable toxicity was achieved, or tumor progression was observed. Of 232 patients randomized, 227 were treated. PLDaun was dosed to 116

patients, while 111 patients received ABV. A statistically significant difference in the response rate or median survival time was not observed among the treatment arms.

### Comments

Most low-risk patients, as defined by the ACTG, showed regression of epidemic (AIDS-related) KS lesions with HAART alone. High-risk patients often required a combination of HAART and chemotherapy, with discontinuation of chemotherapy upon disappearance of clinically relevant disease.

### Drawbacks

**Neutropenia** The most common adverse event in both arms of an RCT comparing PLDox with ABV chemotherapy was leukopenia, affecting 36% of 133 patients who received PLDox and 42% of 125 patients in the ABV group [58]. Grade 3 neutropenia, with an absolute neutrophil count (ANC) between 500 and 1000 cells/mm<sup>3</sup>, was similar in PLDaun- and ABV-treated groups (36% vs 35%, respectively), but grade 4 neutropenia (ANC < 500) was more common in the PLDaun-treated group within the same randomized trial (15% vs 5%;  $P = 0.021$ ) [59].

**Cardiotoxicity** Of 24 patients who received a cumulative dose of >500 mg/m<sup>2</sup> of PLDaun in one randomized study, none were found to have a 20% or greater decline in their left ventricular ejection fraction (LVEF) [59]. In another randomized clinical trial of PLDox versus ABV, pre- and posttreatment estimations of LVEF were available for 47 patients, and just two patients were found to have had a >20% decrease in LVEF [57]. In this same study, just one death was attributed to cardiomyopathy out of 133 patients treated with the PLDox. It would appear that, unlike traditional agents, the pegylated anthracyclines are not associated with marked cumulative cardiotoxicity.

**Nausea and vomiting** Of the patients receiving PLDaun, 51% experienced mild nausea [59]. Grade 3 nausea and vomiting were significantly more frequent with ABV than with PLDox (34% vs 15%;  $P < 0.001$ ) [57].

**Alopecia** In two different randomized trials for treatment of KS, alopecia occurred significantly more often among patients who received ABV chemotherapy than those who received pegylated anthracyclines [57,59].

**Peripheral neuropathy** In two different randomized trials for treatment of KS, peripheral neuropathy occurred significantly more often among patients who received ABV chemotherapy than those who received pegylated anthracyclines [57,59].

**Acute infusion reactions** In three studies of pegylated anthracyclines for KS, acute infusion reactions in just 2% (two of 116) and 5% (six of 133) and 4% (five of 121) patients [57–59]. These acute reactions included flushing, chest pain, hypotension, and back pain. In most cases, premedication to ameliorate these reactions allowed for continued use of pegylated anthracyclines [57], but in one case a severe anaphylactic reaction occurred with PLDox [58].

### Comments and implications for practice

Three large trials suggest that pegylated anthracyclines are at least as effective, if not more effective, in AIDS-related cutaneous KS as standard ABV or BV combination chemotherapy [57–59].

Furthermore, a superior toxicity profile exists for the pegylated anthracyclines. Although there are no randomized, controlled trials directly comparing the two liposomal agents (PLDox and PLDaun), there is reason to believe the response rate for patients with advanced epidemic (AIDS-related) KS may be higher with PLDox.

#### **Implications for practice**

Evidence suggests that PLDox is beneficial for the palliative treatment of advanced epidemic (AIDS-related) KS. Because of a superior toxicity profile, PLDox should be used as first-line systemic therapy for patients with advanced epidemic (AIDS-related) KS. However, the liposomal anthracyclines are quite expensive and are not readily available in developing countries. No recent trials of chemotherapy exist in the other types of KS, but case reports and case series suggest that classic KS or endemic (African) KS is as chemosensitive as AIDS-related disease.

#### **What are the effects of antiretrovirals in the treatment of epidermic (AIDS-related) Kaposi sarcoma?**

Three cohort studies (one small prospective cohort, one larger retrospective cohort, and one large prospective cohort) examined the effect of HAART on epidemic (AIDS-related) KS [60–62]. A small clinical trial compared HAART plus PLDox with the HAART alone [63].

#### **Efficacy**

HAART, which includes two nucleoside reverse transcriptase inhibitors with either a non-nucleoside reverse transcriptase inhibitor or one or two protease inhibitors, has altered substantially the natural history of epidemic (AIDS-related) KS. In fact, widespread adoption of HAART has greatly decreased the observed incidence of KS [34–36], and population-based studies throughout the world have demonstrated that HAART has decreased the incidence of KS as an AIDS-defining illness [64–66].

A small, randomized, open-label study compared HAART plus PLDox with HAART as treatment for moderate to advanced epidemic (AIDS-related) KS [63]. PLDox–HAART patients received a median of 11 cycles of intravenous PLDox treatment. After 48 weeks of follow-up, ITT analysis indicated that nonresponses, partial responses, and complete responses occurred in 4, 6, and 3 patients respectively in the HAART–PLDox group and in 2, 1, and 12 patients in the HAART-alone group, respectively ( $\chi^2$  test 9.5;  $P = 0.008$ ), with a significant difference in the number of partial responders with PLDox–HAART. The investigators concluded that HAART therapy alone does not provide adequate treatment for some patients with moderate to advanced KS.

In a more recent and larger prospective cohort, the effect of HAART was examined in 254 consecutive patients (96% men) diagnosed with epidemic (AIDS-related) KS between 1996 and 2008 (with a median follow-up of over 4 years) [62]. At the time of diagnosis of KS, only 19% patients were on HAART, and only 7% patients had an undetectable plasma viral load for HIV. HAART alone was utilized for management in 163 patients with KS (stage T0), and only one died of KS. Only 37 patients (22%) required adjunctive chemotherapy, yielding a systemic treatment-free survival at 5 years of 74% (95% CI, 67–82), and an overall survival at 5 years of 91% (95% CI, 87–95). The investigators concluded that there was a high success rate of HAART alone in a large cohort of AIDS patients with KS, followed over a prolonged period time, and

that this approach is both well tolerated and effective, particularly for KS (stage T0).

This more recent work augmented an earlier, smaller, prospective cohort study, involving 39 patients with epidemic (AIDS-related) KS treated with HAART, that reported complete and partial response rates of 46% and 28% at 24 months utilizing this treatment modality alone [60]. Additionally, retrospective analysis had already documented a reduced time to relapse of epidemic (AIDS-related) KS when HAART was initiated (0.5 years vs 1.7 years) [61].

#### **Drawbacks**

The side effects profile of HAART depends chiefly upon the individual drugs used and any potential interactions with other drugs the patient is taking. More common side effects include nausea, vomiting, lethargy, diarrhea, peripheral neuropathy, headache, aberrant liver function and elevation of transaminases, hypersensitivity reactions, myelosuppression, lactic acidosis, and pancreatitis.

#### **Implications for practice**

HAART prevents development of KS in patients with HIV, and it has also dramatically decreased the incidence of KS as an AIDS-defining illness. There is evidence that HAART alone may induce regression of individual KS lesions through different postulated mechanisms (immune reconstitution, inhibition of HIV replication, anti-angiogenic and anticytokine effects). Patients with high viral loads, low CD4 counts, or with other HIV-related symptoms require antiretroviral therapy for control of HIV infection. HAART alone in these patients is a reasonable initial therapy for KS, which may be combined later with other local or systemic treatments, particularly in those with more extensive and/or aggressive disease.

#### **Key points**

- HAART therapy has had a significant impact in decreasing the prevalence and severity of epidemic (AIDS-related) KS.
- For many cases of epidemic (AIDS-related) KS, initiation of HAART therapy alone may be adequate therapy, although occasionally moderate to severe disease will require an adjunctive intervention.

#### **Local therapy**

- In classic KS and epidemic (AIDS-related) KS, radiotherapy is likely to improve cosmetic outcome of individual cutaneous lesions, with minimal harm. The optimum dose fractionation schedule in these conditions is yet to be determined, and is beyond the domain of dermatology, but with hypofractionated regimens the potential cutaneous side effects and/or complications may be more substantial.
- Topical imiquimod may have some modest efficacy in treating KS, and it is a drug widely available and familiar to the practicing dermatologist.

#### **Systemic therapy**

- Systemic IFN- $\alpha$  is likely to be beneficial for some cases of epidemic (AIDS-related) KS and this agent can be safely combined with antiretroviral therapy.
- This regimen would seem best suited as first-line therapy for patients with CD4 counts  $>200 \times 10^6$  cells/L, no “B-type” symptoms, and no history of prior opportunistic infections.
- Evidence exists that PLDox is more effective in epidemic (AIDS-related) KS than standard combination chemotherapy.
- Unlike conventional anthracyclines, liposomal anthracyclines do not appear to be associated with cumulative cardiotoxicity.

# Melanocytic nevi

Varun Shahi and Jerry D. Brewer

Mayo Medical School, Mayo Clinic, Rochester, MN, USA

## Background

### Definition

Melanocytic nevi are benign proliferations of melanocytes located at different skin levels. Acquired nevi are generally smaller than 1 cm, whereas congenital ones are usually larger [1]. Pigmentation in different shades of brown can range from a brown–yellowish to brown–blackish color; sometimes – as in mature cellular nevi – they can be skin-colored.

### Classification

Melanocytic nevi, either congenital or acquired, can be classified relative to the histological location of melanocytes into a:

- *junctional nevus*, if the melanocytes are located at the dermoepidermal junction;
- *dermal nevus*, if the melanocytes are in the dermis;
- *compound nevus*, if the melanocytes are at both of the above locations.

A new clinical classification for acquired nevi has recently been proposed, based on dividing them into common and atypical nevi; this approach is particularly useful for stratifying the risk of melanoma. *Common nevi* are neoformations with a maximum diameter of 6 mm, with symmetrical shape and with a homogeneous pigmentation. *Atypical nevi* instead have a larger diameter and at least two of the following parameters: irregular borders (edges) and/or not well defined, asymmetric shape, irregular pigmentation, erythema, and accentuation of the cutaneous design (Figure 37.1) [2]. It is also possible to diagnose an atypical nevus when some or all of the “ABCD” criteria for melanoma diagnosis are present: asymmetry, irregular borders, heterogeneous color, diameter larger than 6 mm [3]. Using this definition, it can sometimes be very difficult to distinguish between atypical nevi and early melanoma, even with the adoption of recent noninvasive techniques such as dermoscopy [4]. In doubtful cases of this type, the lesions should be removed for histological verification.

A congenital nevus is a “melanocytic nevus that has existed since one’s birth”; however, a lesion with the same clinical and pathological characteristics as a congenital nevus can also appear within the first 2 years of life. In this case it is called “nevus tardive” [5].

Congenital nevi are normally classified in accordance with diameter into small (<1.5 cm), medium (1.5–19.9 cm), and large

(>20 cm); the so-called giant nevi are congenital nevi that involve entire anatomic areas (Figure 37.2) [6].

In congenital nevi, melanocytes are typically located on the lowest two-thirds of the dermis. Occasionally, they extend into the subcutaneous tissue, with isolated cells or groups of cells within the reticular dermis collagen fibers, with a tendency to be located around cutaneous appendages. However, many congenital nevi do not show these histopathological characteristics, resulting in a picture not dissimilar to that of acquired nevi; this happens most frequently with small congenital nevi [7].

### Incidence, prevalence, and etiological factors

In people with the same complexion (i.e., similar skin and eye color and ability to tan), the average nevus density varies in accordance with sun exposure. A study on English twins reported that those who spent at least 410 days by the sea in sunny places had 41 nevi/m<sup>2</sup> on average, whereas those who did not expose themselves at all only had 24 nevi/m<sup>2</sup>. Larger acquired nevi (≥5 mm) were more common in boys than in girls [8].

A multicenter Italian study on 3127 13–14-year-olds found a higher nevus density in body areas usually exposed to the sun (i.e., face or neck), becoming lower in density in areas of intermittent exposure, and with the lowest density in areas never exposed. A positive correlation was also reported between the number of sunburns and nevus density [9].

Genetic factors are also an important predictor of nevus development. A recent study based on 221 pairs of teenage twins suggested that genetic factors accounted for about 65% of nevus development, involving factors associated with eye color (7%), hair color (6%), and skin color (1%); the remaining 51% appears to be due to other as yet unidentified genetic factors [10].

A multivariate analysis reported that the use of sunscreens does not prevent the development of melanocytic nevi; however, a negative correlation between the amount of clothing used and nevus counts has been found [11]. Sunscreens are discussed in more detail in Chapter 30.

It has been estimated that 1% of newborns have a congenital nevus of any size, whereas giant congenital nevi are very rare. One study including over 500 000 newborns has shown that only one baby in 20 000 has a nevus with a diameter larger than 10 cm [12].

**Figure 37.1** The leg of a child with numerous common and atypical nevi.

Recent longitudinal studies looking at young children further indicate a linear increase, with respect to age, in the density and number of nevi between the ages of 6 and 12, with the rate of increase being higher in boys than in girls [13].

### Disease associations

Various disease associations have been reported with congenital nevi, particularly the larger ones. Leptomenigeal melanocytosis (associated with congenital nevi on the head and neck), meningo-myelocoele, and spina bifida (associated with nevi in the lumbosacral area) are just some of these associations.

There are also reports in the literature of an association between nevi and ocular malformations and glaucoma, auricular malformation, angiomatous lesions, bone atrophy, and neurofibromatosis [7].

### Prognosis

The natural history of melanocytic nevi is still not fully understood. For acquired nevi, an initial development stage is observed within the first two to three decades of life, with an increase in nevus density afterwards, followed by a plateau. Then, in older age, there appears to be a density reduction, probably due to spontaneous regression of some nevi.

Melanocytic nevi can sometimes regress spontaneously during childhood or adolescence. This premature regression is commonly due to immunological mechanisms, as observed when a ring of depigmentation occurs around the nevus (halo or Sutton's nevus).

It is worth mentioning that some varieties of nevi arise at specific ages. For example, the Spitz nevus typically develops in childhood, while Reed's spindle-cell nevus typically occurs in women in their thirties.

**Figure 37.2** Large congenital nevus of the trunk in a girl (13 years old). The lesion is checked every 6 months.

## Diagnosis

### Clinical examination

Most nevi are easy for expert dermatologists to diagnose by clinical examination alone [14]; whenever there are doubtful cases (differential diagnosis with melanoma), dermoscopy (also known as dermoscopy or epiluminescence microscopy) can be performed in order to increase the diagnostic accuracy. However, dermoscopy is not 100% accurate, and if there is any remaining diagnostic doubt, an excisional biopsy followed by histological examination is recommended. An incisional biopsy is sometimes carried out if the lesions are very large.

### Dermoscopic examination

Dermoscopy is a noninvasive technique that enables the observer to examine some morphological characteristics of the lesion that are not visible with the naked eye. In expert hands, dermoscopy improves the diagnostic accuracy for nearly all pigmented skin lesions in comparison with naked-eye examination [15,16].

Digital dermoscopy also makes it possible to record digital images of specific lesions. This may help in investigating the natural history of a lesion for research purposes, or to follow up a doubtful lesion in order to identify any early malignant behavior. However, the extent to which digital follow-up of a doubtful lesion should be considered an advisable procedure is still a matter of debate [17]. The use of digital follow-up instead of immediate excisional biopsy is associated with a small risk of leaving a melanoma unexcised, with serious consequences. The risk can increase if patients do not comply with regular follow-up surveillance [18,19].

With regard to the impact of adding dermoscopy to melanoma screening, one controlled randomized trial showed that dermoscopy is associated with a significant reduction in the biopsy rate in comparison with a control group undergoing conventional naked-eye examination only (odds ratio [OR], 0.54; 95% confidence interval [CI], 0.30–0.88) [17]. It is possible, therefore, that large-scale use of dermoscopy in melanoma screening may be associated with increased specificity in the diagnosis of melanoma, with fewer false-positive cases and consequently fewer surgical excisions for the purpose of diagnostic verification.

## Relevant outcomes

There are three main reasons for removing a melanocytic lesion. The first is to prevent a possible melanoma when there is a doubtful lesion, the second is to relieve discomfort (e.g., a mole rubbing a bra strap), and the third is for cosmetic purposes. Removing clinically banal nevi in order to reduce the incidence of melanoma is disputable practice; the risk of malignant degeneration of a nevus is in fact extremely low.

## Controversy

The term dysplastic nevus describes a histological finding referring to potential precursors of melanoma, first coined in 1980 by Greene *et al.* in support of the multistep tumorigenesis theory [20–22]. The basis of this theory is credited to Leslie Foulds and describes tumor development and progression from histologically normal melanocytes moving to hyperplasia to nevus to dysplastic nevus and ultimately progressing to melanoma [22]. Similarly, it has been proposed that dysplastic nevi “fit nicely into the schema of progression from hyperplasia to dysplasia to neoplasia that is accepted in many epithelial tumor systems, both experimental and human” [20]. The controversy lies in that some published data lack empirical data to support a multistep tumorigenesis theory – citing hypothetical instead of evidence-based data [23].

Many argue the use of the term “Clark nevus” instead of “dysplastic nevus” [24], in honor of Wallace H. Clark who initially described dysplastic nevus; however, this is still up for debate [25].

Despite this, there is a lack of consensus amongst dermatologists in the use of proper nomenclature, and the term dysplastic nevus continues to refer to precursors to malignancy, by many [21]. Furthermore, the progression of dysplastic nevi to melanoma is implicit in the common practice of classifying nevus as mild, moderate, or severe. To make matters worse, the terms “dysplastic nevus” and “atypical nevus” have been used synonymously in the literature. Studies indicate that these terms are, in fact, not synonymous, making it essential to clarify the distinction between “dysplastic nevus” (which refers to histological findings) and “atypical nevus” (which refers to a clinical description) [26,27].

Many studies suggest that patients with dysplastic nevi are at a much higher risk of developing melanoma compared with the general population [28–32]; however, most dysplastic nevi will never progress to melanoma [33,34]. Additionally, recent studies show that this risk is no higher in patients with dysplastic nevi than it is in patients with common nevi [35–38].

## Management of dysplastic nevi

Practices among physicians differ considerably when it comes to the management of dysplastic nevi [39]. The majority of dermatologists recommend yearly examinations in these patients. Studies indicate that therapeutic treatments such as 5-fluorouracil [40], isotretinoin [41], imiquimod [42,43], tretinoin [44], and laser ablation [45] are not effective in getting rid of or treating dysplastic nevi.

Since moderate to low-grade dysplastic nevi are not likely to reoccur [46,47], it is not advised to perform re-excision without compelling evidence for malignancy through histological or clinical features, especially if the intent of the original biopsy was to remove the nevus in its entirety [48]. Similarly, prophylactic removal of atypical nevi has not been shown to reduce the risk of developing melanoma [49]. Studies indicate, however, that 86% of dermatologists aim to completely remove the entire dysplastic nevi as part of the biopsy, yet dysplastic nevi are re-excised based on positive histological margins by 67% of dermatologists [39]. We advise institu-

tions and dermatopathologists using the graded system of mild, moderate, and severely atypical that severely atypical nevi require a standard re-excision with 5 mm margins even if no margins are involved, histologically, in the original biopsy specimen.

The authors’ institution has devised an atypical nevus specialty clinic and working group that has devised this proposed algorithm in dealing with the management of this controversial area in cutaneous medicine (see Figure 37.3).

## Methods of search

The databases of the Cochrane Library, Medline, and Embase between 1951 and April 2013 were searched for articles that (a) studied the relationship between nevi and (b) the risk of subsequent melanoma in congenital nevi of various sizes. The search was carried out by combining the following key words: melanocytic nevi, dermoscopy, epiluminescence microscopy, skin self-examination (SSE) and epidemiology, case-control, meta-analysis.

## Questions

### What is the risk of a melanocytic nevus developing into a melanoma?

It has been suggested that, because the high frequency of melanocytic nevi contrasts with the low incidence rate of nevus-associated melanoma (about 20–30% of all melanomas) [50], the transformation of an acquired nevus into a melanoma should be considered a very rare event, with an estimate of about one nevus out of 200 000 per year for people younger than 40 years of age and one nevus out of 33 000 per year for men over 60 years of age [9]. Little is known about the role of malignant transformation of a preexisting nevus in determining the increased risk of melanoma in people with many nevi. According to a case-control study that compared the risk factor profile of patients with nevus-associated melanoma (cases) with that of patients with melanoma de novo (controls), a large number of nevi were associated with a significantly higher risk for melanoma in the former than in the latter group of patients [51]. A history of many sunburns was more strongly associated with nevus-associated melanoma than with melanoma de novo. This finding lends support to the role of sunburn in increasing the risk of neoplastic progression of nevus cells. These results are based on a single study and need to be confirmed by further independent studies.

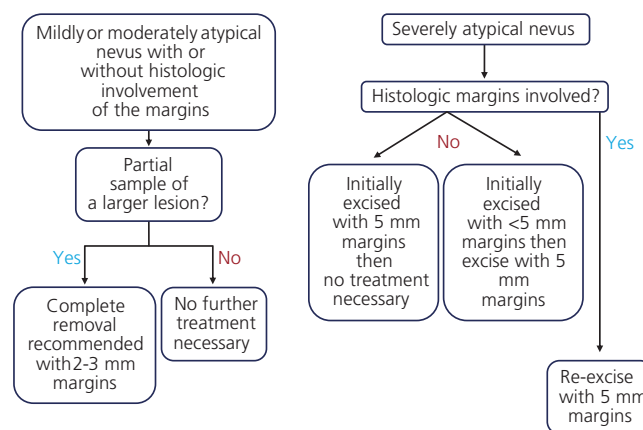

Figure 37.3 Algorithm for atypical nevus revision.

With regard to congenital nevi, their natural history appears to be strongly correlated with the lesion size. A prospective analysis of 80 children affected by large congenital nevi (diameter >20 cm) who were followed up for 5 years showed a malignant degeneration rate of 3.8% [52].

Subsequent research on 92 children (maximum age 3 years) with a large congenital nevus who were followed up for 5.4 years reported the occurrence of three melanomas, all of which were located in extracutaneous areas (the central nervous system and retroperitoneal region). This finding is explained by the possible existence of melanocytic hamartomas in noncutaneous areas such as the meninges and retina in some people with giant congenital nevi.

According to the data on giant melanocytic nevi, the risk of developing a melanoma within the first 5 years of life is 4.5% (95% CI, 0–9.3%), with a standardized incidence ratio over the expected number of the overall population equal to 239 [53].

More controversial than giant nevi is the behavior of congenital nevi with a diameter less than 20 cm. The transformation of intermediate (diameter between 1.5 and 19.9 cm) and small (diameter <1.5 cm) into melanoma is uncommon [54]. Though the specific risk is not currently known, recent prospective studies did not find any associations [55,56]. Still, some authors suggest that malignant transformation of such medium-sized lesions rarely if ever occurs before adulthood [52]. Further prospective cohort studies are needed to provide reliable data on the malignant transformation rate of small and intermediate-sized congenital nevi.

### **How should a patient with an isolated congenital nevus be managed?**

There are no widely accepted guidelines on how to deal with congenital nevi [57] – which is not surprising, given the lack of accurate epidemiological evidence regarding their rate of malignant transformation. If clinical suspicion exists, the prophylactic removal of a small congenital nevus can be carried out usually fairly easily.

For medium-sized congenital nevi, the risk of malignant transformation is probably significant, but has not been precisely estimated [52]. However, medium-sized nevi are technically difficult to remove because of their size, and when they are removed they can leave a large and cosmetically unacceptable scar. The logical consequence of this dilemma is that this type of congenital nevus is often managed by regular visits to the doctor, supplemented by instructions being given to parents or to patients to check the lesion frequently, supplemented by photography and measurements to use as a baseline for future examinations.

The management of giant melanocytic nevi poses many difficulties, and the timing of surgery, if contemplated, may be important. Some authors suggest neonatal curettage [58]. The curettage must be carried out during the first month of life, when it is easy to identify the cleavage plane between the nevus and the normal tissue below. However, it is difficult to achieve histological clearance of the nevus, and a risk of malignant transformation still persists. Some authors have suggested that it is easier to identify malignant transformation after curettage than after conventional surgery, because new pigmented lesions are easier to visualize on “normal” skin after curettage [59].

Unfortunately, while there is an increased risk of melanoma in people with large congenital nevi, there is currently no scientific evidence that traditional surgical intervention reduces the risk of melanoma [60]. The cosmetic effects of extensive surgery and grafting for giant melanocytic nevi in early life can be disappointing and

may be complicated by painful scars, through which deeper melanocytic nevi may emerge after many years.

The presence of a larger congenital nevus, often on the upper side of the trunk and the head and associated with leptomeningeal melanocytosis, is a contraindication to surgical removal of the lesion, as the risk of melanoma persists in these areas [4].

### **How should a patient with multiple melanocytic nevi be managed?**

There is a close correlation between the number of melanocytic nevi and the risk of melanoma; according to one of the numerous case–control studies reported in the literature, the OR of melanoma associated with more than 45 nevi is 9.7 (95% CI, 5.4–17.4) [61]. There is, therefore, an argument that people with approximately 50 nevi should visit a dermatologist at least once a year for surveillance purposes [61]. The presence of atypical nevi, which are often present in people with numerous common nevi and phototype I or II, is another risk factor for melanoma that may require regular surveillance [10].

One approach is to teach such patients how to carry out self-examination of the skin. Self-examination allows features such as changes in shape and color to be identified at an early stage. One multicenter Italian survey of melanoma cases suggested that this procedure was associated with a reduction in the risk of late diagnosis of melanoma (thickness >1 mm), even after adjustment for confounding factors such as sex, age, and anatomic area of the lesion (OR, 0.70; 95% CI, 0.50–0.97) [11]. Berwick *et al.* conducted a case–control study to investigate the relationship between SSE and a reduced risk of fatal melanoma. They found that self-examination is associated with a reduced risk of melanoma incidence (OR, 0.66; 95% CI, 0.44–0.99) and with a possible reduced risk of advanced disease among melanoma patients (unadjusted risk ratio, 0.58; 95% CI, 0.31–1.11) [62].

There is no good evidence to suggest that trauma to benign nevi will increase the risk of malignant transformation. Moreover, stratification of nevi on the basis of their risk of transformation is not currently possible. Indeed, there is no good evidence that nevi that have an “atypical” appearance from a clinical point of view should be considered precursors of melanoma. Some clinically atypical nevi can show histological atypia (otherwise known as “dysplastic nevi”). However, even banal nevi can show histological atypia, since the correlation between clinical and histological atypia in nevi is poor [63].

The approach known as the “mole-mapping technique” – that is, recording images of all melanocytic lesions on the body and subsequently following them up to identify early possible malignant change – is a controversial procedure [17,18]. It is probably useful for periodic follow-up of people who are at high risk of melanoma. There is no evidence of any benefit of this technique in other situations, in comparison with examining the patient without analyzing the baseline characteristics of all the nevi.

## **Skin self-examination**

### **How commonly is skin self-examination done and what factors predict regular skin self-examination?**

Since SSE may be useful in reducing the rate of late presentation of melanoma [11], it is possible that promoting SSE in the general population might reduce the overall mortality from melanoma. The

American Cancer Society recommends a monthly SSE, a clinical skin examination every 3 years for those over the age of 20, and a clinical examination every year for those over the age of 40.

Little is known about how many people currently perform SSE. In an Australian study, SSE within the previous 12 months was reported by more than 25% of healthy people contacted by means of a telephone interview [64].

In a study in Connecticut, SSE was noted in 13.2% of melanoma patients and in 17.5% of controls [62]. In an Italian study, 40.5% of people visiting a pigmented-lesion clinic reported that they performed SSE [65]. The higher rates of SSE in the latter study are probably explained by the fact that the participants were examined at a specialized pigmented-lesion clinic aimed at providing melanoma screening and follow-up for those at increased risk of melanoma.

An important point is the frequency of SSE. In a random survey of the adult population in Rhode Island, USA, Weinstock *et al.* found that only 9% of recalled individuals performed a thorough skin examination at least once every few months [66]. Oliveria *et al.* found that 6.0% of men and 7.0% of women performed “rigorous” SSEs [14].

It is important to identify which factors increase the likelihood of an individual performing SSE, as it may help in refining educational strategies for melanoma prevention. Oliveria *et al.* found that skin awareness was a strong factor associated with SSE for both women and men (OR, 4.65 in men; 95% CI, 2.11–11.46; OR, 2.53 in women; 95% CI, 0.91–8.31). For women, variables significantly associated with SSE included previous benign biopsy or the presence of an abnormal mole (OR, 4.22; 95% CI, 1.72–12.01). In men, a family history of cancer (OR, 2.02; 95% CI, 1.02–4.13), physician examination (OR, 3.44; 95% CI, 1.77–6.94), and a change in diet to reduce the cancer risk (OR, 2.17; 95% CI, 1.12–4.23) increased the likelihood of SSE [14]. The Italian study used a multivariate model that adjusted for eye color, phototype, large numbers of common and atypical melanocytic nevi, sunscreen use, and having had a previous examination and having received a leaflet explaining SSE. The study found that, in men, the only variable significantly associated with SSE was a report of having received a leaflet explaining SSE (OR, 3.02; 95% CI, 1.24–7.38). For women, it was a report of having already had a previous consultation at a pigmented-lesion clinic (OR, 4.84; 95% CI, 1.57–14.93); the latter may be secondary to the explanations and advice about skin cancer prevention usually provided at a previous visit [65].

Weinstock *et al.* [15] evaluated the impact of participation in a mole-mapping program on the performance of thorough SSE. They found that 45% of those who were not performing SSE before participation reported performing it after receiving their images. However, 30% had never used the images to assist them in the self-examination. This study has important limitations: there was a small number of participants and the sample chosen only included a high-risk population.

### How accurate is skin self-examination?

In a cohort study of people at high risk of melanoma, Feit *et al.* showed that 32% of the malignancies were diagnosed because patients reported concern about the lesions – suggesting that patients were competent in identifying suspicious lesions using SSE [16].

Other papers confirm that most melanomas are discovered by the patient: 42–47% of men and 59–69% of women with melanomas reported that their melanomas were self-detected [17,67,68].

In a recent population-based study including 3772 Queensland residents with melanoma, McPherson *et al.* [18] found that 44.0% of the patients reported first noticing the melanoma themselves, whereas 25.3% of the melanomas were first noticed by a doctor, 18.6% by partners, and 12.1% by other laypersons (including other relatives, friends, and service people). In comparison with men, a greater proportion of women detected their melanomas themselves (57.1% vs 33.8%), whereas men had a greater proportion of partner-detected melanomas (26.7% vs 8.1%). Most commonly, the signs and symptoms reported by patients who are later found to have melanoma are changes in the color, size, or shape of a lesion, or an irritation or itch; they also report that the lesion looked different from other spots [18].

The sensitivity of SSE for certain risk factors for melanoma was studied by Gruber *et al.* [69]. They identified freckles, palpable nevi, and large nevi as potential risk factors for the development of cutaneous malignant melanoma. The sensitivity of self-reporting of the number of freckles on the right forearm was found to be 88%. The sensitivity was 63% for detecting one or more palpable arm nevi and 68% for detecting one nevus larger than 5 mm in diameter on the entire body.

Muhn *et al.* [70] studied the sensitivity of detecting an artificial increase in the size (0, 2, or 4 mm in diameter) of a preexistent nevus on the back using SSE. The patients examined their backs with a mirror before and after the manipulation of the mole. At this point, the patient was asked to determine which mole, if any, had been changed. They found that the sensitivity for detecting a 2 mm change was approximately 58% (95% CI, 49–68%). The sensitivity for detecting a 4 mm change was approximately 75% (95% CI, 66–83%). The specificity of the test (i.e., the ability to detect no change) was approximately 62% (95% CI, 53–72%). These results relate to a difficult area for body examination (on the back) and are thus likely to represent the worst-case scenario for the sensitivity and specificity of SSE for detecting changes in the size of a nevus, although this group of patients were highly selected and motivated. Another limitation of this study is that it only assessed changes in the size of the nevus, whereas it is a combination of changes in shape, thickness, and color, as well as the development of new moles, that allows patients to detect a malignant lesion.

A recent study by Oliveria *et al.* [71] investigated the sensitivity and specificity of SSE for detecting new and changing moles with or without the aid of baseline digital photographs in patients with dysplastic nevi. They found that the sensitivity and specificity of SSE for detecting both new and altered moles without photography were 60.2% and 96.2%, respectively, whereas SSE with photography showed significant improvements in diagnostic accuracy, with a sensitivity and specificity of 72.4% and 98.4%, respectively.

Weinstock and co-workers [72] tested the ability to detect an additional 5 mm pigmented lesion on the back. To improve the accuracy of SSE, they required half of the participants to complete a mole-mapping diagram (intervention group). They found that 33% of the control group and 52% of the intervention group ( $P = 0.06$ ) gave accurate assessments. Participants in the intervention group were better able to identify the added lesion or lesions ( $P = 0.01$ ).

SSE is associated with a reduced incidence of advanced melanoma, but it is prone to error in detecting early melanoma changes. Improving the accuracy of SSE may therefore be important in allowing detection of melanoma at an earlier stage and thereby reducing the mortality.

## Key points

- Nevus density is related to sun exposure and genetic factors.
- Dermoscopy improves the diagnostic accuracy for nearly all pigmented skin lesions in comparison with naked-eye examination and may reduce the rate of unnecessary biopsies when used for melanoma screening.
- Nevi may be surgically removed because of discomfort or appearance, or to exclude melanoma or prevent melanoma from occurring.
- There is a link between an increased number of melanocytic nevi and the risk of subsequent malignant melanoma.
- The rate of malignant degeneration of small congenital nevi (<1.5 cm) is unknown and is difficult to estimate because of their similarity to acquired melanocytic nevi.
- Congenital nevi with a diameter >20 cm have an approximately 4% risk of melanoma developing.
- Clinically, atypical nevi are a risk factor for melanoma.
- Removal of giant melanocytic nevi may not be associated with a reduced risk of melanomas, which may appear in noncutaneous sites, and surgical procedures such as grafting are often complicated by scarring and subsequent breakthrough pigmentation.
- Self-examination in people with large numbers of moles probably reduces the risk of late diagnosis of melanoma (thickness >1 mm).
- Approximately 50% of the population probably detect their own melanomas – women more frequently than men.

## SECTION 3 Infective skin diseases, exanthems, and infestations

Masutaka Furue and Yuping Ran, editors

### CHAPTER 38

## Local treatments for cutaneous warts

Juping Chen<sup>1</sup> and Yan Wu<sup>2</sup>

<sup>1</sup>Department of Dermatology, Second Clinical Medical College of Yangzhou University, Yangzhou, China

<sup>2</sup>Department of Dermatology, No.1 Hospital of China Medical University, Shenyang, China

### Background

#### Definition

Cutaneous warts are extremely common, benign, and usually self-limiting. Infection of epidermal cells with the human papilloma virus (HPV) results in cell proliferation and a thickened, warty papule on the skin. The most common sites involved are hands and feet, though any area of skin can also be infected. Genital warts are also common and frequently sexually transmitted, but are not discussed in this chapter.

#### Prevalence

There are few reliable, population-based data on the prevalence of cutaneous warts. The prevalence rate varies according to different ages, populations, and periods of time, and it is the highest in children and young adults. Two large population-based studies revealed prevalence rates of 0.84% and 12.9% [1,2]. Studies in school populations showed rates of 12% in 4–6-year-olds and 24% in 16–18-year-olds [3,4].

#### Etiology and risk factors

Warts are caused by HPV, of which there are over 70 different types. Lesions are most common at sites of trauma, and probably result from inoculation of virus into minimally damaged areas of epithelium. Plantar warts are often acquired from common bare-foot areas; severe hand warts showed an occupational risk in butchers and meat handlers [5,6].

#### Prognosis

Non-genital warts in immunocompetent people are harmless and usually resolve spontaneously as a result of natural immunity within months or years. The rate of resolution is highly variable and probably depends on a number of factors, including host immunity, age, HPV type, and site of infection. One frequently cited study of an institutionalized population showed that two-thirds of warts resolved within a 2-year period [7]. Evaluation of clearance rates in

control groups in randomized controlled trials (RCTs) may also give some indication of natural clearance tendency, although a non-specific benefit of vehicle bases may make interpretation difficult. Twenty-three RCTs discussed in this chapter showed an average cure rate of 18% (range 0–73%) with placebo preparations after an average period of 10 weeks (range 4–24 weeks).

#### Diagnostic tests

Warts are frequently diagnosed clinically. Microscopic examination obtained surgically can confirm the diagnosis if there is doubt. HPV typing is used in research laboratories and occasionally in medico-legal cases to investigate child abuse.

#### Aims of treatment

To clear warts completely and permanently.

#### Relevant outcomes

- Cure rate (total clearance rate);
- recurrence;
- adverse reactions, such as pain and blistering.

#### Methods of search

##### Data sources and search strategy

All RCTs on the topical treatments for extragenital warts were identified, without limitation of language or publication status. The Medline, Embase, Cochrane Library, the Meta Register of Controlled Trials, CBM, and CNKI were searched. Reference lists of prior reviews, systematic reviews, and trials were also checked. The most recent searches were completed in June 2012.

#### Study selection and data extraction

Two investigators independently screened studies for inclusion, retrieved potentially relevant studies, and determined eligible studies. Disagreements were resolved by consensus. Two investigators independently extracted data from the included studies using

custom-made standardized forms and a third investigator was assigned with the checking process.

### Quality assessment

The criteria recommended by the *Cochrane Collaboration Handbook* were used to assess the methodological quality of included trials. It mainly focused on description of randomization (sequence generation progress), allocation concealment, blinding, addressing of incomplete outcome data, reporting of selective outcome, and other potential threats to validity [8]. The judgment for each entry was based on the answer of a question, with “yes” indicating “low risk of bias,” “no” indicating “high risk of bias,” and “unclear” indicating “either lack of information or uncertainty over the potential for bias” [8]. Disagreements were resolved by group consensus.

### Outcomes measurement

The primary outcome is the cure rate (total clearance rate). The secondary outcome is adverse reactions.

### Statistical analysis

All statistical analyses were performed using the duplicate data entry facility of Revman 5.0.25 (evidence-based medicine software) by two investigators [9]. In addition to 95% confidence intervals (CIs), relative risks (RRs) and mean differences (MDs) were respectively used for dichotomous and continuous outcomes. The  $\chi^2$  (chi-square test) statistic was calculated to determine the proportion of between-study variation due to heterogeneity. The value ranged from 0 to 100%, and high values indicated strong heterogeneity. If heterogeneity was low ( $P > 0.1$ ,  $\chi^2 < 50\%$ ), a fixed-effect model was used, otherwise a random-effect model was used. Intention to treat (ITT) was done for efficacy evaluation, and per-protocol (PP) analysis was done for adverse reaction evaluation.

## Results

### Salicylic acid or topical products containing salicylic acid

#### Efficacy

##### *Salicylic acid versus placebo*

Five RCTs [10–14] compared salicylic acid (SA) with placebo. SA preparations gave a higher cure rate of 73% versus that of 48% with placebo. The RR was 1.60, 95% CI was 1.16–2.23, number needed to treat (NNT) was 4 (95% CI, 3–7).

##### *Salicylic acid versus cryotherapy*

Three RCTs [15–17] compared SA with cryotherapy. The cure rates were respectively 60% and 70% in the two groups, and no significant difference was seen between the two treatments (RR, 0.85; 95% CI, 0.59–1.21).

#### Other comparisons

Seven RCTs [15,18–21] compared different products containing SA or compared SA with other topical treatments, such as glutaraldehyde and dithranol. The heterogeneous trials showed no convincing advantage of any particular delivery system for SA.

### Drawbacks

Generally, topical SA was reported to have no significant harmful effects. In one RCT that compared a mixture of monochloroacetic acid and 60% SA with placebo [13], one of the 29 patients in the

active treatment group developed cellulitis. Minor skin irritation was noted occasionally in some trials.

### Comments

There is reservation about the validity of pooled data from the different RCTs, because of the generally low quality of trials and the heterogeneity of their design and methodology. For instance, the RCTs included used different topical SA products, or some RCTs included patients with refractory warts whereas others excluded them. Despite this, we consider that there is good evidence for a modest benefit of SA in treating non-genital warts.

### Cryotherapy with liquid nitrogen

#### Efficacy

##### *Cryotherapy versus placebo or no treatment*

Two small RCTs compared cryotherapy with either placebo cream [22] or no treatment [23]. One of the two trials [22] reported a very low cure rate for cryotherapy (one of 11), while the other trial [23] showed a high cure rate in the placebo group (eight of 20). The pooled data of cure rates did not demonstrate a significant difference between the cryotherapy group and control group: 35% versus 34% (RR, 0.88; 95% CI, 0.26–2.95).

##### *Cryotherapy versus salicylic acid*

Three RCTs [15–17] compared SA with cryotherapy. The results have already been mentioned in the section entitled “Salicylic acid versus cryotherapy.”

##### *Cryotherapy versus bleomycin*

Two RCTs compared cryotherapy with intralesional bleomycin [24,25]. Because of heterogeneity of methodology and design, the two trials are described separately. One trial [24], which used 1 mg/mL bleomycin, obtained cure rates of 76.5% in the cryotherapy group and 94.9% in the bleomycin group (RR, 0.18; 95% CI, 0.03–0.90,  $P = 0.04$ ). Another RCT [25], using 0.5 mg/mL bleomycin, had a cure rate of 68.2% in the cryotherapy group and 100% in the bleomycin group (RR, 1.27 ( $1 < \text{RR} < 1.6$ );  $P < 0.05$ ).

#### Length of freeze

Four RCTs [26–29] compared aggressive and gentle cryotherapy in 592 adults and children. However, the definitions of “aggressive” and “gentle” used differed, and some studies included refractory warts whereas others did not. Overall, cure rates were 52% with aggressive cryotherapy and 31% with gentle cryotherapy (RR, 1.90; 95% CI, 1.15–3.15; NNT, 5; 95% CI, 3–7).

#### Interval between freezes

Three RCTs [15,30,31] showed no significant difference in cure rates among 2-week, 3-week, and 4-week intervals. Cure was generally achieved more quickly with shorter treatment intervals.

#### Optimum number of freezes

Only one RCT [32] examined this question in 115 adults and children who did not cure 3 months after 3-weekly cryotherapy and showed no benefit of prolonging cryotherapy for a further 3 months. The cure rates were 43% and 38% in the treated and untreated groups, respectively (no data available for calculating the odds ratio).

### Drawbacks

Only two RCTs included precise data on adverse events. Pain or blistering was reported by 64 of 100 participants (64%) treated with an “aggressive” (10 s) regimen, in comparison with 44 of 100

participants (44%) treated with a “gentle” (brief freeze) regimen (RR, 1.45; 95% CI, 1.12–2.31). Five participants withdrew from the aggressive-regimen group and one from the gentle-regimen group because of pain and blistering [26]. Pain or blistering was reported in 29%, 7%, and 0% of those treated at 1-week, 2-week, and 3-week intervals, respectively (no data available for the odds ratio) [30]. The rate of reported adverse affects was relatively high with a shorter interval, but this is likely to be a reporting artifact, as these participants were seen sooner after each treatment.

### Comments

The evidence from the available RCTs of cryotherapy for warts is limited and contradictory. Just as the RCTs on topical SA, the heterogeneities of study designs, methods, and populations make it difficult to draw firm conclusions from the pooled data. For instance, some trials included all types of warts on the hands and feet in all age groups, whereas others were more selective and simply focused on hand warts, or excluded certain groups such as those with mosaic plantar warts or refractory warts. Of particular note is the likelihood that the “populations” in these studies may have very different characteristics at different periods of time. For example, studies conducted in the 1970s in the UK would have included a higher proportion of participants with incident warts, which have a greater chance of cure or spontaneous resolution. In the 1980s and 1990s, more people with warts were treated in primary care. Thus, clinics would have had a more selected population with a higher proportion of refractory warts and correspondingly lower cure rates.

### Occlusive treatment with duct tape

#### Efficacy

##### *Duct tape versus placebo*

Two published trials did this comparison and did not show good cure rates with duct tape [33,34]. The trial by De Haen *et al.* [33] included 103 primary-school children who were randomly assigned to continuous duct tape and a no occlusive corn pad once a week. After 6 weeks, recurrence occurred in eight of 51 (16%) versus three of 52 (6%) of the trial warts. Curiously, other untreated warts resolved in 21% and 27% of the children, respectively. Wenner *et al.* [34] conducted a trial comparing occlusive duct tape (obscured by a sticky-backed fabric called moleskin) with the moleskin alone in 90 adult patients (the trial population had an unusually high age of 54 years). After 8 weeks, relapse occurred in eight of 39 (21%) versus nine of 41 (22%), respectively. Among the cured patients, six of eight (75%) and three of 10 (30%), respectively, had relapsed again after 6 months.

##### *Duct tape versus cryotherapy*

One trial compared occlusive treatment with duct tape and cryotherapy in 61 children and young adults [35]. The duct tape was applied for 6.5 days every 7 days, cryotherapy was given for 10 s every 2–3 weeks up to a maximum of six times. The cure rates were 22 of 30 (71%) and 15 of 31 (46%), respectively (RR, 1.52; 95% CI, 0.99–2.31). There were limitations to the trial: the number of patients was relatively small, 10 s of cryotherapy was inadequate, an unspecified number of outcome assessments were carried out over the phone, and it was not entirely clear how long after the treatment period was done.

### Drawbacks

Duct tape is simple, safe, and cheap. No significant adverse events were mentioned in any of these trials.

### Comments

None of these three trials are strong methodologically; thus, the results are somewhat contradictory and difficult to summarize meaningfully.

### Contact immunotherapy with dinitrochlorobenzene

#### Efficacy

Two small RCTs [22,36] of dinitrochlorobenzene (DNCB) in 80 children and adults achieved a cure rate of 80% (32/40) in comparison with 38% (15/40) in the placebo/no treatment groups (RR, 2.12; 95% CI, 1.38–3.26; NNT, 2; 95% CI, 2–4).

### Drawbacks

One trial [36] commented that six of 20 participants treated with 2% DNCB were sensitized only after the second application. All of them subsequently experienced significant local irritation, with blistering, when they were treated with 1% DNCB. None withdrew from the study.

### Comments

DNCB, a potent contact allergen, can cause significant local irritation and dermatitis, which probably precludes its use outside specialist centers.

### Photodynamic therapy

#### Efficacy

##### *Photodynamic therapy versus placebo*

One trial [37] randomized active (proflavine+black light) and placebo (picric acid + black light) treatments for recalcitrant symmetrical verrucae vulgaris, on the left and right sides of the body. The result showed no significant difference. Three trials [38–40] compared 5-aminolevulinic acid (ALA)-photodynamic therapy (PDT) with placebo-PDT, and all patients locally used keratolytic. Meta-analysis showed no significant difference (RR, 1.53; 95% CI, 0.86–2.73).

##### *Photodynamic therapy versus salicylic acid*

One RCT [41] including 120 adults and children compared methylene blue/dimethyl sulfoxide PDT with a mixture of SA and creosote. The cure rates were 8% and 15%, respectively.

##### *Photodynamic therapy versus cryotherapy*

In one RCT [42], four different types of light source for PDT were compared with cryotherapy. Topical SA was used for all patients. More warts were completely healed after white light-PDT than after red/blue light-PDT and cryotherapy.

##### *5-Aminolevulinic acid-photodynamic therapy versus high-frequency electrocautery*

One RCT [43] including 60 patients with plantar warts did this comparison. The cure rates of ALA treatment group were 37.5% (12 of 32 patients) and 17.86% (five of 28 warts), which were higher than those of the high-frequency electrocautery treatment group.

##### *5-Aminolevulinic acid-photodynamic therapy+salicylic acid versus microwave therapy*

One trial [44] including 126 plantar warts patients showed the cure rates were similar between two groups, while the recurrence rate was lower in the ALA treatment group than that in the microwave treatment group.

### **5-Aminolevulinic acid–photodynamic therapy versus semiconductor laser**

One RCT [45] reported that ALA–PDT is superior to semiconductor laser (cure rates 25/28 vs 18/28).

### **Methyl aminolevulinate–photodynamic therapy+chemical keratolytic treatment versus chemical keratolytic treatment**

One trial [46] evaluated methyl aminolevulinate (MAL)–PDT with or without chemical keratolytic treatment for hand warts in a population of renal transplant patients. The number of vanished warts showed no significant difference between two treatments.

### **5-Aminolevulinic acid–photodynamic therapy+CO<sub>2</sub> laser versus CO<sub>2</sub> laser**

In one trial [47], a total of 70 patients with plantar warts were randomly divided into two groups. The cure rates were 48.6% (17 of 35 patients) and 20% (seven of 35 warts) in ALA–PDT+CO<sub>2</sub> laser treatment group, higher than those of CO<sub>2</sub> laser treatment group.

### **Side effects**

One RCT [48] focused on the pain induced by PDT of warts, by filling in questionnaires about pain immediately and 24 h after each treatment. Forty-five patients were enrolled in a randomized, placebo-controlled trial with six consecutive ALA- and placebo–PDT treatments for recalcitrant foot and hand warts. Severe or unbearable pain was reported from a median of 17% (6–31%) of the ALA-treated warts and from a median of 2% (0–15%) from the placebo-treated warts immediately after the treatments. With increasing treatments, no significant change in pain intensity was observed, no significant relation was found between the pain intensity and the relative change in wart area. The pain was primarily characterized as burning and shooting. The pain lasted about 30 h (range: 1–96 h).

Nine RCTs [38–40,42–47] reported the side effects during or after the PDT treatment. Pain, burning, itching, local anesthesia, swelling, and erythema were common; most were mild/moderate and acceptable. No treatments were suspended because of pain.

### **Comments**

The fact that most trials used different protocols of PDT (different photosensitizer, different light sources, different treatment intervals, and so on) makes it difficult to draw a definite conclusion. So far, PDT appears to offer no particular advantages in cure rates or adverse effects than other simpler and cheaper local treatments available. But for recalcitrant warts, it might be an alternative approach, which should be proved by further research.

## **Intralesional bleomycin**

### **Efficacy**

#### **Bleomycin versus placebo**

Conflicting results were reported in five RCTs of intralesional bleomycin. Three trials [49–51] reported higher cure rates with bleomycin than with placebo, one [52] showed that placebo was associated with higher cure rates than bleomycin, and one [53] showed no significant differences between bleomycin and placebo. The pooled results showed that bleomycin was more effective than placebo in the treatment of cutaneous warts (RR, 3.84; 95% CI, 2.19–6.71).

#### **Bleomycin versus cryotherapy**

Two RCTs [24,25] compared liquid-nitrogen cryotherapy with intralesional bleomycin. The results were shown in the section “Cryotherapy with liquid nitrogen.”

### **Different concentrations of bleomycin**

One RCT [54] in 26 adults, comparing 0.25, 0.5, and 1.0 IU/mL bleomycin, showed cure rates of 73%, 88%, and 90% of warts, respectively; the differences were not statistically significant.

### **Drawbacks**

No precise data on adverse effects were provided in any of the RCTs. One RCT [52] reported “adverse events” in 19/62 (31%) participants, but the nature of the adverse events and the proportions in the active treatment and placebo groups were not specified. Three of the trials [49,50,54] reported that most participants experienced pain. In two trials [50,51], local anesthetic was used routinely before the injection of bleomycin. One trial [54] reported pain was seen in most participants, which was irrespective of dose. In one trial [49] of 24 participants who received bleomycin, two patients withdrew because of the pain of the injections and pain in the period after the injection.

### **Comments**

Again, methodological and statistical heterogeneity (different outcomes, trial periods, units of analysis, numbers of injections, vehicles, and concentrations) make it impossible to organize the data from these trials.

## **5-Fluorouracil**

### **Efficacy**

#### **5-Fluorouracil versus placebo**

One RCT [55] compared 5-fluorouracil with placebo. Altogether, 60 patients (including 40 children) were randomized to be treated with topical 5-fluorouracil for 4 weeks and placebo. During the procedure, 31 patients were lost to the active treatment and the cure rate was 60%, versus three lost to the placebo treatment and the cure rate was 17%. There were statistically significant difference between the two treatments (RR, 7.44; 95% CI, 2.86–19.35).

#### **5-Fluorouracil cryotherapy versus cryotherapy+placebo**

One RCT [56] compared cryotherapy combination with 5-fluorouracil and cryotherapy combination with placebo; the cure rates were 58.57% and 65.29% respectively. There was no significant difference (RR, 0.55; 95% CI, 0.22–1.40).

#### **5-Fluorouracil+duct tap versus duct tape**

One RCT [57], including 40 patients, treated with 5-fluorouracil combined with duct tape and duct tape alone for 12 weeks. The cure rates were 95% (19/20) and 10% (2/20) respectively (RR, 9.50; 95% CI, 2.54–35.51).

### **Drawbacks**
